Chapter 1

Introduction

160 The issue of fairness in machine learning has recently risen to prominence due to its implications in real-world decision-making systems (MEHRABI *et al.*, 2021; HUTCHINSON e MITCHELL, 2018). Addressing biases and discrimination is a relevant frontier in decision-making systems, as equitable outcomes across various demographic groups is both an ethical imperative and often a legal require-
165 ment. Though fairness is a multifaceted concept, it has been deeply examined within the context of machine learning. The literature presents a variety of fairness definitions, drawing concepts from political philosophy and computational techniques (HUTCHINSON e MITCHELL, 2018; CATON e HAAS, 2023). Choosing an equitable machine learning model requires the selection of a fitting definition of
170 fairness, tailored to the specific problem at hand. Many such definitions can be precisely articulated, allowing models to be evaluated based on their predictions.

One inherent challenge in fair machine learning is the balance between fairness and accuracy. Efforts to mitigate unfairness often compromise the model’s predictive performance, a trade-off that has been well documented (MEHRABI *et al.*, 2021;
175 CATON e HAAS, 2023). Predictors that are less biased against marginalized groups may deviate from the true class, resulting in sub-optimal performance. Also, introducing fairness considerations adds constraints to the model, further complicating the optimization process (ZAFAR *et al.*, 2017a).

In light of these challenges, we introduce the Fair Transition Loss, a novel ap-
180 proach to fair classification. This method estimates the influence of historical and societal biases on outcome probabilities for distinct groups within dataset. For instance, individuals from marginalized groups might have lower chances of favorable outcomes compared to their counterparts from privileged groups. Such disparate probabilities can be represented by transition matrices. Drawing inspiration from
185 label noise robustness, we incorporate these transition matrices information into the loss function to promote fairness. The proposed method has some hyperparameters, chosen by a Multi-Objective Optimization approach combining both fairness and

model performance with a linear smooth objective. This objective is defined in such a way that it is possible to use this approach to optimize a variety of fairness and performance metrics.

The primary contribution of this study is the conceptualization of the Fair Transition Loss, a novel loss function influenced by label noise methodologies. In benchmark tests across common fair classification tasks, our empirical results demonstrate that this method consistently outperforms many leading in-processing fair classification techniques in a variety of scenarios. The novelty of this work lies in applying label noise techniques directly within the model to mitigate unfairness. As far as we know, this is the first time that label noise techniques are directly used to address fairness in machine learning.

Chapter 2

205 Fair machine learning

The field of Machine Learning (ML) has experienced significant growth and is increasingly applied in various societal domains such as healthcare, finance, and criminal justice. This growth raises important ethical and operational concerns, particularly regarding the principles of Fairness, Accountability, and Transparency (FAT) (MEMARIAN e DOLECK, 2023). As ML algorithms increasingly influence a wide array of societal domains, including criminal justice, healthcare, finance, and employment, the requirement to ensure these systems are designed and implemented responsibly has become paramount. This section aims to delineate the significance, scope, and prevailing challenges associated with integrating FAT principles into ML, providing a foundation for the subsequent discussion.

Fairness in ML concerns the equitable and just treatment of all individuals, particularly those from historically marginalized or disadvantaged groups (MEHRABI *et al.*, 2021; CATON e HAAS, 2023). It seeks to ensure that ML algorithms do not perpetuate existing biases or create new forms of discrimination. However, the multifaceted nature of fairness, encompassing various definitions and metrics, poses substantial challenges in operationalizing it within algorithmic frameworks. Further in this section we will explore these complexities, examining different conceptions of fairness and the inherent trade-offs they entail.

Accountability in ML pertains to the obligation of designers, developers, and maintainers of ML systems to be answerable for the outcomes of these systems (HUTCHINSON *et al.*, 2021). It involves establishing mechanisms that allow for the tracing of decisions back to the entities responsible for the deployment of the ML algorithms. Accountability also encompasses the adherence to ethical standards, legal requirements, and societal norms. This discussion frequently involves mechanisms and practices that can promote accountability in ML, like auditing, documentation, and regulatory compliance.

Transparency, the third pillar, refers to the clarity and openness with which ML systems operate (BURKART e HUBER, 2021). It involves the ability of stakehold-

ers, including end-users, regulators, and the broader public, to understand how ML
235 systems make decisions. Transparency is mandatory property of any automated de-
cision making system to achieve trustworthiness, facilitating informed consent, and
enabling the scrutiny necessary to identify and rectify biases. However, achieving
transparency, particularly with complex models, presents its own set of technical
and ethical challenges. This research topic includes issues as the trade-off between
240 explainability and model performance, and discussing emerging approaches to tackle
interpretability without sacrificing effectiveness.

The triad of Fairness, Accountability, and Transparency (FAT) along with data
privacy forms the cornerstone of Trustworthy Artificial Intelligence (TwAI). These
principles are pivotal in ensuring that AI systems are developed and deployed in
245 a manner that respects human rights, promotes social well-being, and maintains
public trust. While accountability ensures that entities behind AI systems can be
held responsible for their outcomes, transparency allows stakeholders to produce
and maintain environments where AI systems can be scrutinized, understood, and
corrected, thereby aligning their functionality with societal norms and values.

250 In this context of Trustworthy AI the European Union’s High-Level Expert
Group on Artificial Intelligence has outlined seven key principles that aim to en-
sure that AI systems are designed and used in a way that is ethically sound and
trustworthy (HLEG, 2019). These principles are fundamental for developing and
maintaining decision making systems that are beneficial and avoid unintended harm.
255 The seven principles are as follows:

Human agency and oversight AI systems should empower human beings, allow-
ing them to make informed decisions and fostering their fundamental rights.
At the same time, proper oversight mechanisms need to be ensured, which
can be achieved through human-in-the-loop, human-on-the-loop, and human-
260 in-command approaches

Technical Robustness and safety AI systems need to be resilient and secure.
They need to be safe, ensuring a fall back plan in case something goes wrong,
as well as being accurate, reliable and reproducible. That is the only way to
ensure that also unintentional harm can be minimized and prevented.

265 **Privacy and data governance** besides ensuring full respect for privacy and data
protection, adequate data governance mechanisms must also be ensured, tak-
ing into account the quality and integrity of the data, and ensuring legitimized
access to data.

Transparency the data, system and AI business models should be transparent.
270 Traceability mechanisms can help achieving this. Moreover, AI systems and

their decisions should be explained in a manner adapted to the stakeholder concerned. Humans need to be aware that they are interacting with an AI system, and must be informed of the system’s capabilities and limitations.

Diversity, non-discrimination and fairness Unfair bias must be avoided, as it could have multiple negative implications, from the marginalization of vulnerable groups, to the exacerbation of prejudice and discrimination. Fostering diversity, AI systems should be accessible to all, regardless of any disability, and involve relevant stakeholders throughout their entire life circle.

Societal and environmental well-being AI systems should benefit all human beings, including future generations. It must hence be ensured that they are sustainable and environmentally friendly. Moreover, they should take into account the environment, including other living beings, and their social and societal impact should be carefully considered.

Accountability Mechanisms should be put in place to ensure responsibility and accountability for AI systems and their outcomes. Auditability, which enables the assessment of algorithms, data and design processes plays a key role therein, especially in critical applications. Moreover, adequate and accessible redress should be ensured.

Although there are many aspects to consider to an ethical automated decision system with social impacts, the present text will concentrate predominantly on the aspect of fairness and negative social bias. Fairness is not only desirable for the development of just and equitable technological solutions but an obligation for maintaining the trustworthiness and acceptability of AI systems in diverse societal contexts.

2.1 Sources and types of algorithmic unfairness

The comprehensive survey conducted by MEHRABI *et al.* (2021) elucidates the multitude of biases that can pervade artificial intelligence applications, potentially leading to unfair outcomes. This analysis categorizes the various sources of bias, illustrating the multifaceted ways in which such biases can infiltrate different stages of machine learning processes, ranging from the initial data collection phase to the final algorithmic processing. The following exposition provides a short delineation of these sources of bias. To a rich discussion on this topic - including references, examples and real cases where each source of bias can emerge - we recommend the reading of the original work. The discussion here is with the purpose of proper

305 describing the complexity and multifaceted nature of unfairness in machine learning models.

Historical Bias This is the existing societal bias that reflects past and present inequalities and prejudices. Historical bias is present in the data even before any machine learning model has interacted with it, due to inherent social and cultural inequalities;
310

Representation Bias Occurs when the data sample does not accurately represent the entire population or certain subgroups within it. This can lead to machine learning models that perform well on majority groups but poorly on underrepresented groups;

315 **Measurement Bias** Arises when the data collected does not accurately measure the real-world constructs it purports to measure. This type of bias can occur due to flawed data collection instruments or processes that systematically misrepresent certain groups;

Evaluation Bias This type of bias occurs during the performance evaluation of machine learning models, where the evaluation criteria or methods may favor one group over others, leading to biased assessments of model performance;
320

Aggregation Bias Happens when incorrect assumptions are made about the homogeneity of groups within the data. Aggregation bias can lead to misleading conclusions if the differences within and between groups or subgroups are not properly accounted for;
325

Population Bias Similar to representation bias, population bias occurs when statistics, demographics, representatives, and user characteristics are different in the user population represented in the dataset, leading to models that are not generalizable across different demographic groups;

330 **Simpson's Paradox** This is a statistical phenomenon where a trend appears in several different groups of data but disappears or reverses when these groups are combined;

Longitudinal Data Fallacy Occurs when cross-sectional data is treated as longitudinal, leading to incorrect conclusions about data trends over time;

335 **Sampling Bias** Introduced by non-random sampling procedures, where certain members of the intended population are less likely to be included in the sample than others, leading to skewed data that does not accurately represent the entire population;

Behavioral Bias Arises from variations in user behavior that differ across different platforms or contexts, affecting the data's representation of real-world phenomena;

Content Production Bias Results from differences in how content is generated by different groups, with structural, lexical, semantic, and syntactic differences, influencing the data available for machine learning models;

Linking Bias Occurs in networked data, where the connections between nodes can misrepresent the true attributes or behavior of the nodes;

Temporal Bias Reflects changes in data characteristics over time, due changes in representation or behaviors, which may not be accounted for in static machine learning models;

Popularity Bias Occurs when popular items are more likely to be recommended or rated highly, not necessarily because of their quality but simply because of their initial, higher visibility and these popularity metrics are subject of manipulation;

Algorithmic Bias Introduced by the algorithms themselves, when they add bias that was not present in the input data:

User Interaction Bias Results from the way system design influences user behavior in biased ways. This source of bias can be influenced by other types or subtypes, such as Presentation and Ranking Biases:

Presentation Bias This bias occurs when the way information is presented influences the outcomes. In machine learning, this can manifest through the design of user interfaces or the manner in which data is displayed, affecting user decisions and interactions;

Ranking Bias Arises when algorithms prioritize certain data points over others in ranked lists or search results, which can distort visibility and perpetuate certain preferences or discriminations;

Social Bias Social biases are the preconceived notions and stereotypes held by societies, where individual actions or contents are socially influenced. These biases often find their way into data through collective social behaviors and decisions, influencing the training data used for machine learning models;

Emergent Bias Emerges during the operation of a system, particularly as a result of changes in population, cultural values, or societal knowledge in the data over time. This type of bias is dynamic and can occur even if the initial model was unbiased, due to changes in the underlying data or context;

Self-Selection Bias Occurs when the individuals selected for a study or dataset have self-selected in some way, producing a sample that is not representative of the general population. This can skew results and make the data less generalizable;

Omitted Variable Bias Happens when a model overlooks certain relevant variables that are correlated with both the independent and dependent variables. Omitting these variables can lead to incorrect inferences about correlations and effects;

Cause-Effect Bias This bias is a misunderstanding in the determination of causation; it can occur when correlations are mistaken for causal relationships without proper justification through causal inference techniques;

Observer Bias Introduced by the expectations or preconceptions of those collecting or processing data, which can influence the outcomes subconsciously;

Funding Bias Refers to the influence that the source of funding can have on the conduct of research or development of algorithms. This type of bias can lead to results that favor the interests of the funding source, consciously or unconsciously.

These biases can pervade various stages of machine learning, from data collection to model evaluation and deployment, highlighting the importance of understanding and mitigating bias to achieve fairness in AI systems. Furthermore, the presence of biases can lead to feedback loops that exacerbate these inequalities over time. When biased data influence the decisions made by an AI system, these decisions can then be used to generate more data, which, if used to retrain the model, may reinforce and even amplify the existing biases. This cycle can create a self-perpetuating loop, making initial biases more entrenched and difficult to correct. Addressing feedback loops is critical, as they can progressively deteriorate the fairness of the system, leading to increasingly skewed outcomes that are harder to rectify. Effective strategies to break these loops include rigorous monitoring of model decisions, regular updates to training datasets to ensure diversity and representativeness, and the implementation of mechanisms that can detect and correct for emerging biases

Having outlined the various sources of unfairness in machine learning, MEHRABI *et al.* (2021) also explores different types of discrimination that arise from these biases. Understanding these types of discrimination is pivotal as they elucidate how biases, whether direct, indirect, systemic, statistical, explainable, or unexplainable, can culminate in unfair outcomes. Each type of discrimination demonstrates a distinct pathway through which biases embedded in data or algorithms manifest

410 in practices and decisions, thus potentially perpetuating unfairness in AI systems. This comprehensive analysis helps in identifying targeted strategies to mitigate these discriminatory effects and underscores the importance of developing automated decision systems that are both just and equitable.

Direct Discrimination occurs when outcomes are directly affected by sensitive
415 attributes such as race, gender, or age. This type of discrimination happens explicitly and is frequently legally prohibited;

Indirect Discrimination manifests when proxy attributes indirectly linked to sensitive attributes influence outcomes. For example, using zip codes in decision-making processes might inadvertently reflect racial biases because residential
420 areas often correlate with racial demographics. This phenomena is also referred as redlining effect (PEDRESCHI *et al.*, 2008);

Systemic Discrimination involves policies or practices entrenched within an organization that perpetuate disadvantage for certain groups. This can stem from cultural biases embedded in the decision-making processes, often reflecting
425 the preferences or biases of dominant groups;

Statistical Discrimination refers to the use of general statistics on a group to make inferences about individuals from that group. This type of discrimination might arise when decision-makers use visible characteristics as proxies for other traits, leading to biased assessments;

430 **Explainable Discrimination** is considered legally permissible if the differences in treatment or outcomes can be justified through legitimate and relevant attributes. For instance, differences in pay might be justified by the number of hours worked if this factor significantly influences earnings;

Unexplainable Discrimination occurs when there is no justifiable reason for the
435 disparate treatment or outcomes, making it illegal and ethically unacceptable. This type of discrimination requires interventions to ensure fairness and equality in decision-making processes.

2.2 Fairness definitions and metrics

This section aims to present some widely used definitions and metrics of fairness, as
440 described by VERMA e RUBIN (2018) and summarized by MEHRABI *et al.* (2021) and CATON e HAAS (2023), providing a comprehensive overview for understanding and navigating the multifaceted dimensions of fairness in ML systems. Initially, we explore general considerations and intuitive aspects of fairness, setting the stage

for a deeper understanding. This preliminary discussion lays the groundwork for
445 understaining the nuanced nature of fairness notions within the context of ML.
Following this, we will transition into formal definitions, where we will dissect and
explain those metrics and concepts.

Even before this discussion, we emphasizes that no single fairness definition uni-
versally applies to all scenarios. The choice of a particular fairness definition and
450 metric should be informed by ethical considerations grounded in the social context
in which the model would be deployed (ALER TUBELLA *et al.*, 2022). Selecting
a fairness definition is not a purely technical matter, as it inevitably requires eth-
ical and social considerations that should not be neglected (ALVES *et al.*, 2023).
Building fair machine learning models requires an interdisciplinary approach that
455 engages all stakeholders, including specially those who are typically marginalized or
underrepresented (WEINBERG, 2022).

A prevalent taxonomy within fairness literature differentiates fairness notions
into group metrics and individual metrics. Group Fairness Metrics hinge on the
principle that statistical measures — such as error rates, precision, and recall —
460 ought to be equitably distributed across groups demarcated by sensitive attributes
like race, gender, or age. The core premise of these metrics is that fairness is actual-
ized when an algorithm exhibits consistent performance across diverse demographic
segments.

Demographic Parity, for example, mandates uniformity in the rate of positive
465 algorithmic outcomes across different groups, a standard that remains agnostic to
the underlying base rates within each population segment. On the other hand,
Equal Opportunity and Equalized Odds introduce a nuance to this conversation by
tethering fairness to the true condition of outcomes. This refinement delineates a
central differentiation within fairness metrics: some are predicated solely on pre-
470 dicted values (such as Demographic Parity), while others derive from the scope of
the confusion matrix (Table 2.1), also incorporating true value conditions (as seen
in Equal Opportunity and Equalized Odds).

Individual Fairness Metrics, in contrast, introduce a more granular perspective
to fairness, advocating that similar individuals should be treated similarly by the
475 ML system. This approach diverges from group-level considerations, focusing in-
stead on ensuring that the algorithm’s treatment is consistent for individuals who
are alike in relevant aspects, barring their membership in different demographic cat-
egories. Individual fairness seeks to ensure a personalized sense of justice, where the
algorithmic outcomes are solely reflective of pertinent attributes rather than biased
480 by irrelevant factors associated with sensitive attributes. This concept champions
the notion that fairness extends beyond group identities to recognize and respect
the uniqueness of individual experiences and qualifications.

To establish the foundation for discussing fairness definitions and metrics, we commence with an examination of the confusion matrix, which is an essential instrument in machine learning to assessing the performance of classification algorithms. It constitutes a tabular visualization that delineates the correspondence between the true labels and the predicted outcomes generated by a model. For binary classification tasks, the confusion matrix is structured into four principal components: True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN), as outlined in Table 2.1. By providing a clear breakdown of these outcomes, the confusion matrix allows to calculate many key performance metrics such as accuracy, precision, recall, and the F1 score, providing comprehensive insights into the strengths and weaknesses of the classification model. Also, the computation of those metrics forms the basis for evaluating fairness across distinct demographic groups.

Table 2.1: Confusion matrix of binary classification outcomes

		Predicted	
		Positive	Negative
Actual	Positive	TP	FN
	Negative	FP	TN

True Positives (TP) can be defined as the probability that the predictor correctly identifies a positive outcome when the true condition is positive. Using the conditional probability notation, it is expressed as $P(\hat{Y} = 1|Y = 1)$, indicating the probability that the predicted class \hat{Y} is positive given that the actual class Y is positive.

False Positives (FP) represent the probability that the predictor incorrectly identifies a positive outcome when the true class is negative. It is denoted as $P(\hat{Y} = 1|Y = 0)$, reflecting the probability that the predicted class \hat{Y} is positive when the actual class Y is negative.

False Negatives (FN) are defined as the probability that the predictor incorrectly identifies a negative outcome when the true class is positive. This is given by $P(\hat{Y} = 0|Y = 1)$, the probability that the predicted class \hat{Y} is negative given that the actual class Y is positive.

True Negatives (TN) correspond to the probability that the predictor correctly identifies a negative outcome when the true condition is negative. In conditional probability terms, it is $P(\hat{Y} = 0|Y = 0)$, indicating the probability that the predicted class \hat{Y} is negative given that the actual class Y is negative.

Now we proceed to more complex metrics that provides complementary insights into the performance of the classifier. These derived metrics, such as Positive Predictive Value (PPV), False Discovery Rate (FDR), and others, constitutes the basic elements of the confusion matrix to quantify the reliability of the predictions in

various ways. By expressing these metrics in terms of conditional probabilities and confusion matrix components, we facilitate a comprehensive analysis of the classifier's behavior, providing resources to a proper evaluation of its fairness across different demographic groups.

520 **Definition 1** (Positive Predictive Value (PPV)). *PPV, or precision, measures the proportion of correctly identified positive outcomes among all predicted positives. It is defined as the probability that the true condition is positive given the predicted condition is positive, $P(Y = 1|\hat{Y} = 1)$. In terms of the confusion matrix, PPV is calculated as $\frac{TP}{TP+FP}$, the ratio of true positives to the sum of true positives and false*
 525 *positives.*

Definition 2 (False Discovery Rate (FDR)). *FDR quantifies the rate of incorrect positive predictions. It is the probability that the true condition is negative when the predicted condition is positive, $P(Y = 0|\hat{Y} = 1)$. From the confusion matrix, FDR is computed as $\frac{FP}{TP+FP}$, indicating the proportion of false positives out of all predicted*
 530 *positives.*

Definition 3 (Negative Predictive Value (NPV)). *NPV assesses the accuracy of negative predictions, representing the probability that the true condition is negative given the predicted condition is negative, $P(Y = 0|\hat{Y} = 0)$. NPV is derived from the confusion matrix as $\frac{TN}{TN+FN}$, the number of true negatives over the sum of true*
 535 *negatives and false negatives.*

Definition 4 (False Omission Rate (FOR)). *FOR indicates the likelihood of a false negative prediction. It corresponds to the probability that the true condition is positive when the predicted condition is negative, $P(Y = 1|\hat{Y} = 0)$. In the confusion matrix context, FOR is $\frac{FN}{TN+FN}$, representing the number of false negatives relative*
 540 *to all predicted negatives.*

Definition 5 (True Positive Rate (TPR)). *TPR, or recall, measures the proportion of actual positives that are correctly predicted. It is the probability that the predicted condition is positive given the true condition is positive, $P(\hat{Y} = 1|Y = 1)$. TPR is calculated as $\frac{TP}{TP+FN}$ in the confusion matrix, the ratio of true positives to the sum*
 545 *of true positives and false negatives.*

Definition 6 (False Negative Rate (FNR)). *FNR quantifies the rate of missed positive predictions. It is defined as the probability that the predicted condition is negative when the true condition is positive, $P(\hat{Y} = 0|Y = 1)$. FNR is derived from the confusion matrix as $\frac{FN}{TP+FN}$, indicating the proportion of false negatives out of the actual*
 550 *positives.*

Definition 7 (True Negative Rate (TNR)). *TNR, or specificity, indicates the accuracy of negative predictions, representing the probability that the predicted condition is negative given the true condition is negative, $P(\hat{Y} = 0|Y = 0)$. From the confusion matrix, TNR is computed as $\frac{TN}{TN+FP}$, the number of true negatives to the sum of true negatives and false positives.*

Definition 8 (False Positive Rate (FPR)). *FPR assesses the likelihood of incorrect negative predictions, calculated as the probability that the predicted condition is positive when the true condition is negative, $P(\hat{Y} = 1|Y = 0)$. FPR is given by $\frac{FP}{TN+FP}$ in the confusion matrix, the ratio of false positives to the sum of true negatives and false positives.*

As we transition from foundational metrics that directly stem from the confusion matrix, such as PPV and TPR, we now discuss standard performance metrics that assess classification models in a more comprehensive manner. These metrics, such as Accuracy and F1 are distinguished by their reliance on both classes to provide a more holistic evaluation.

Definition 9 (Accuracy (Acc.)). *Probably the most widely used performance metric to classification problems, Accuracy is the proportion of true results, both true positives and true negatives, among the total number of cases examined. In terms of conditional probabilities, accuracy reflects the probability that the predicted condition is correct, both as a positive and negative outcome, given the actual conditions, and can be expressed as*

$$P(\hat{Y} = Y) = P(\hat{Y} = 1|Y = 1) \cdot P(Y = 1) + P(\hat{Y} = 0|Y = 0) \cdot P(Y = 0).$$

Using the confusion matrix, accuracy is computed as

$$\frac{TP + TN}{TP + TN + FP + FN}.$$

Definition 10 (Balanced Accuracy (Bal. Acc.)). *Balanced accuracy is an average of the true positive rate (TPR) and the true negative rate (TNR), which compensates for class imbalance by treating both classes equally. Using conditional probabilities, it can be expressed as*

$$\frac{1}{2} \left[P(\hat{Y} = 1|Y = 1) + P(\hat{Y} = 0|Y = 0) \right],$$

where each term represents the conditional probability of correctly predicting the

respective class. In terms of the confusion matrix, balanced accuracy is calculated as

$$\frac{1}{2} \left[\frac{TP}{TP + FN} + \frac{TN}{TN + FP} \right].$$

Definition 11 (F1 Score). *The F1 score is the harmonic mean of precision and recall, providing a balance between the PPV and TPR. It is calculated as $2 \cdot \frac{PPV \cdot TPR}{PPV + TPR}$. Using conditional probabilities and confusion matrix terms, the F1 score can be expressed as*

$$2 \cdot \frac{P(Y = 1|\hat{Y} = 1) \cdot P(\hat{Y} = 1|Y = 1)}{P(Y = 1|\hat{Y} = 1) + P(\hat{Y} = 1|Y = 1)},$$

and calculated using terms from confusion matrix as

$$\frac{2 \cdot TP}{2 \cdot TP + FP + FN}.$$

Definition 12 (Matthews Correlation Coefficient (MCC)). *MCC is a measure of the quality of binary classifications, producing a value between -1 and 1 where 1 is a perfect prediction, 0 no better than random prediction, and -1 indicates total disagreement between prediction and observation. The MCC is defined as*

$$\frac{TP \cdot TN - FP \cdot FN}{\sqrt{(TP + FP) \cdot (TP + FN) \cdot (TN + FP) \cdot (TN + FN)}}.$$

In terms of conditional probabilities, MCC considers all four quadrants of the confusion matrix, correlating the true and predicted conditions. It can be seen as a correlation coefficient between the observed and predicted binary classifications, providing a more informative measure than simple accuracy in the presence of class imbalance.

Now we describe the most widely used group fairness definitions, including statistical parity, equal opportunity, predictive equality, and equalized odds. Demographic parity requires that the likelihood of a positive outcome is the same across different groups, irrespective of their sensitive attributes. Equal opportunity extends this concept to the true positive rate, ensuring that individuals from different groups have an equal chance of being correctly classified as positive. Predictive equality, on the other hand, focuses on the true negative rate, ensuring that individuals from different groups have an equal chance of being correctly classified as negative. Equalized odds combines the principles of equal opportunity and predictive equality, ensuring that both true positive and true negative rates are equal across different groups.

Definition 13 (Statistical Parity). *The likelihood of a positive, i.e., favorable, outcome should be the same in every group of the sensitive attribute (DWORK et al.,*

2012; KUSNER et al., 2017). A binary predictor \hat{Y} satisfies Statistical Parity (a.k.a.
 590 Demographic Parity) if $P(\hat{Y}|A = 0) = P(\hat{Y}|A = 1)$, where A is a protected attribute.

For example, the credit approval probability should be the same for the male and female groups. Demographic Parity does not depend on true class Y , only on prediction \hat{Y} . We can measure Demographic Parity (Definition 13) for a protected attribute A as the absolute difference between $P(\hat{Y}|A = 0)$ and $P(\hat{Y}|A = 1)$, as seen
 595 in Equation 2.1. According Demographic Parity, the predictor is considered fairer when this metric is lower.

$$|P(\hat{Y}|A = 0) - P(\hat{Y}|A = 1)| \quad (2.1)$$

By analyzing the confusion matrix, we can determine the absolute difference between the rates of $(TP + FP)/(TP + FP + TN + FN)$ for both protected and unprotected groups.

600 **Definition 14** (Equal Opportunity). *The probability of a person in a positive class being assigned to a positive, i.e., favorable, outcome should be the same in every group of the sensitive attribute (HARDT et al., 2016). A binary predictor \hat{Y} satisfies Equal Opportunity if $P(\hat{Y}|A = 0, Y = 1) = P(\hat{Y}|A = 1, Y = 1)$, where Y is true class and A is a protected attribute.*

605 Definition 14 claims that protected and unprotected, i.e., privileged, groups should have equal true positive rates. Mathematically, a classifier with equal true positive rates will also have equal false negative rates, so we can analyze the confusion matrix checking whether a predictor has equal $(TP)/(TP + FN)$ or $(FN)/(TP + FN)$ in each group of the sensitive attribute. Like in Demographic
 610 Parity, we can measure Equal Opportunity as an absolute difference between protected and privileged groups, as defined in Equation 2.2.

$$|P(\hat{Y}|A = 0, Y = 1) - P(\hat{Y}|A = 1, Y = 1)| \quad (2.2)$$

Definition 15 (Predictive Equality). *The probability of a person in a negative class being assigned to a negative outcome should be the same in every group of the sensitive attribute. A binary predictor \hat{Y} satisfies Predictive Equality if
 615 $P(\hat{Y}|A = 0, Y = 0) = P(\hat{Y}|A = 1, Y = 0)$, where Y is true class and A is a protected attribute.*

Definition 15 establishes that that both the protected and privileged groups should have the same true negative rates, which consequently results in equal false positive rates. Using a confusion matrix definition, we check the absolute difference
 620 of $(TN)/(TN + FP)$ or $(FP)/(TN + FP)$ between the groups. So, we can measure

Predictive Equality according Equation 2.3.

$$|P(\hat{Y}|A = 0, Y = 0) - P(\hat{Y}|A = 1, Y = 0)| \quad (2.3)$$

Definition 16 (Equalized Odds). *Both probabilities of the person in a positive class being assigned to a positive outcome and of a person in a negative class being assigned to a negative outcome should be the same in every group of the sensitive attribute (HARDT et al., 2016). A binary predictor \hat{Y} satisfies Equalized Odds (a.k.a. Average Odds Difference) if $P(\hat{Y}|A = 0, Y) = P(\hat{Y}|A = 1, Y)$, where Y is true class and A is a protected attribute.*

Equalized Odds is a combination of the principles from Definition 14 and Definition 15, i.e., protected and unprotected groups should have equal true positive and true negative rates, therefore equal false positive and false negative rates. Using a confusion matrix definition, we check the absolute difference between $(TP)/(TP + FN)$ and $(TN)/(TN + FP)$ of predictor in protected and unprotected groups. Equation 2.4 describes how to measure Equalized Odds as the average between Equal Opportunity and Predictive Equality. According to Definition 16, the predictor is considered fairer when this metric is lower.

$$\frac{1}{2} \left[|P(\hat{Y}|A = 0, Y = 1) - P(\hat{Y}|A = 1, Y = 1)| + |P(\hat{Y}|A = 0, Y = 0) - P(\hat{Y}|A = 1, Y = 0)| \right] \quad (2.4)$$

Using the same logic, it is possible to define group fairness metrics based derived from any binary classification metric from confusion matrix. The procedure is the same, assessing the absolute difference from those metrics between protected and unprotected groups.

While individual fairness metrics strive to ensure equitable treatment of individuals based on their specific attributes and circumstances, they may not always capture broader systemic inequalities that affect entire groups. As we pivot our discussion towards group fairness, we examine the potential drawbacks and complications that can arise when pursuing fairness metrics across different demographic groups.

In this context a key challenge is the Simpson’s Paradox (BLYTH, 1972), where trends apparent in separate groups disappear or reverse when these groups are combined. This can lead to misleading conclusions in aggregated data, potentially obscuring significant disparities within subgroups that are averaged out in the analysis. Furthermore, group fairness metrics may inadvertently mask discrimination within protected groups. For instance, a model could satisfy group fairness criteria overall while still discriminating against specific subgroups within a protected class due

to the heterogeneity within larger groups that isn't captured by broader fairness assessments.

655 Additionally, implementing group fairness often involves trade-offs GOH *et al.* (2016); KOMIYAMA *et al.* (2018); PETROVIĆ *et al.* (2021); F.CRUZ *et al.* (2021); LIU e VICENTE (2022) that can impact the overall performance of the predictive model. Balancing fairness with accuracy can lead to difficult choices, especially in high-stakes applications such as healthcare or criminal justice, where the cost
660 of errors is significant. For example, efforts to reduce false positive rates in one group might inadvertently increase false negatives in another, adversely affecting the model's overall predictive utility. Another issue arises from the conflict between different fairness definitions, where improving fairness according to one metric might worsen it according to another. Achieving demographic parity, which calls for equal
665 outcomes across groups, might conflict with ensuring equal opportunity, which demands equal true positive rates across groups. Such conflicts necessitate careful consideration to determine which fairness criteria are most appropriate for specific applications.

Lastly, standard group fairness metrics often overlook intersectionality—the com-
670 plex, cumulative way in which multiple forms of discrimination, such as race, gender, and class, intersect and affect individuals (KEARNS *et al.*, 2017, 2019). Ignoring this aspect can result in policies and models that do not fully address the nuanced ways in which bias manifests. This oversight underscores the importance of individual fairness, a principle that seeks to ensure equitable treatment by focusing on
675 the uniqueness of each individual rather than merely categorizing them into groups. Individual fairness advocates for algorithms to treat similar individuals similarly, regardless of their group membership MEHRABI *et al.* (2021), thus acknowledging and addressing the multifaceted nature of discrimination and ensuring that each person is considered on their own merits. By integrating individual fairness into
680 our models, it is possible to better capture and mitigate the intersecting and often overlapping biases that group fairness metrics might miss, providing a more comprehensive approach to fairness in AI systems

Fairness Through Awareness (DWORK *et al.*, 2012) is a concept which focuses on treating similar individuals similarly. It emphasizes the importance of fairness at
685 the individual level by defining a metric of similarity between individuals based on relevant characteristics, and ensuring that the algorithm's decisions are consistent for individuals deemed similar by this metric. This approach is rooted in the idea that fairness can be achieved by explicitly considering the sensitive attributes through a carefully defined similarity function, ensuring that decisions are justifiable and
690 tailored to individual circumstances.

Definition 17 (Fairness Through Awareness). *A predictor \hat{Y} satisfies Fairness*

Through Awareness if for any two individuals $x, x' \in X$, where X is the domain of individuals, the distance metric $d(x, x')$ under which the individuals are considered similar enforces that $|\hat{Y}(x) - \hat{Y}(x')| \leq d(x, x')$. Here, d is a task-specific metric that
695 measures similarity relevant to the decision-making process, incorporating sensitive attributes where necessary.

This definition implies that the algorithm must incorporate a nuanced understanding of what it means for two individuals to be similar, which goes beyond merely ignoring sensitive attributes. Instead, it considers these attributes in a way
700 that respects individual differences and upholds fairness.

Fairness Through Unawareness CORBETT-DAVIES *et al.* (2018), on the other hand, is a more straightforward approach where an algorithm is considered fair if it does not explicitly use sensitive attributes (such as race, gender, etc.) in the decision-making process. This method assumes that the exclusion of sensitive attributes will
705 prevent discriminatory practices. However, this approach can be naive as it fails to consider that biases can be encoded in other, non-sensitive attributes that are correlated with the sensitive ones MEHRABI *et al.* (2021); CATON e HAAS (2023); HORT *et al.* (2023).

Definition 18 (Fairness Through Unawareness). *A predictor \hat{Y} satisfies Fairness Through Unawareness if the decision function \hat{Y} does not explicitly include any
710 sensitive attribute A as part of the input. In other words, \hat{Y} is constructed without direct knowledge of A .*

Another example of Individual Fairness Metric is the notion of Counterfactual Fairness (KUSNER *et al.*, 2017), which introduce a causal reasoning framework into
715 the fairness discourse. These metrics are based on the concept that a decision is fair towards an individual if the same decision would have been made in a counterfactual world where the individual belonged to a different demographic group but all other characteristics remained constant. This approach hinges on causal models that specify how sensitive attributes affect other features and the outcome. Counterfactual
720 fairness aims to address the individual-level biases that group fairness metrics might overlook, providing a nuanced approach that considers the hypothetical scenarios of individuals belonging to different demographic categories. By employing counterfactual analysis, one can assess whether the disparities in ML predictions stem from legitimate factors or unjust biases. Relevant works approaching this notion
725 include WU *et al.* (2022), MA *et al.* (2023), and GRARI *et al.* (2023).

Definition 19 (Counterfactual Fairness). *A predictor \hat{Y} is counterfactually fair with respect to a protected attribute A if, under any context $X = x$ and $A = a$, the distribution of \hat{Y} is the same in the actual world and a counterfactual world where*

A is set to any permissible value. That is,

$$P(\hat{Y}_{A \leftarrow a}(U) = y \mid X = x, A = a) = P(\hat{Y}_{A \leftarrow a'}(U) = y \mid X = x, A = a),$$

for all y and any value a' of A , where X are the features not causally dependent on A , and U denotes the background variables.

This definition roots itself in the idea that fairness should be preserved across hypothetical alterations of the sensitive attribute, reflecting a robust stance against
730 biases that might otherwise emerge due to such attributes.

Implementing counterfactual fairness involves constructing a causal model that maps how inputs (features including sensitive attributes) influence the outputs (predictions). One must identify which attributes are causally independent of the sensitive attribute and ensure that the predictions are invariant when the sensitive
735 attribute’s values are modified hypothetically.

This approach is particularly pertinent when decisions have substantial impacts on individuals, such as in hiring, loan approval, or healthcare settings. By ensuring that predictions remain consistent regardless of changes to sensitive attributes, models can be designed to mitigate unfair discriminatory practices that could otherwise
740 affect outcomes based on irrelevant attributes.

While the concept of counterfactual fairness is intuitive and persuasive, its implementation poses significant challenges KASIRZADEH e SMART (2021). Building models that reflect the true causal relationships in the data is non-trivial and requires deep domain knowledge. Also, access to good quality data that sufficiently
745 captures the causal dependencies is necessary, which can be a limiting factor in many practical scenarios. Finally, the complexity of calculating counterfactuals, especially in large datasets with many attributes, can be computationally demanding. Despite these challenges, counterfactual fairness pushes the boundaries of fairness in machine learning by providing a framework that directly tackles the underlying
750 causal mechanisms leading to biased decisions.

In the context of fairness definitions and metrics there is a relevant problem to be considered, the Impossibility Theorem. As elucidated simultaneously by KLEINBERG *et al.* (2017) and CHOULDECHOVA (2017) with further contributions by SARAVANAKUMAR (2020), BELL *et al.* (2023) and BEIGANG (2023), articulates
755 a fundamental challenge in the domain of algorithmic fairness: the concurrent satisfaction of distinct fairness metrics is inherently unfeasible under certain conditions. This theorem, also referred to as the Incompatibility of Fairness Criteria, delineates the intrinsic conflicts arising amongst prevalent fairness constructs.

The Impossibility Theorem in the context of algorithmic fairness articulates a
760 fundamental challenge: it is not feasible to simultaneously satisfy multiple fairness

criteria in certain realistic settings. This theorem highlights the inherent conflict that arises when attempting to meet several well-intentioned fairness metrics such as counterfactual fairness, equalized odds, and predictive parity at the same time.

According to the theorem, if a predictive model is designed to achieve counter-
765 factual fairness, it will likely conflict with the criteria of equalized odds or predictive parity. Counterfactual fairness demands that the model’s prediction for an individual would remain unchanged in hypothetical scenarios where the individual’s protected characteristics (such as race or gender) are altered but all other variables are held constant. In contrast, equalized odds require that error rates across different
770 groups are similar, while predictive parity necessitates comparable predictive values across these groups. When protected characteristics are causally relevant to the predicted outcomes, aligning the model with one fairness metric may inadvertently breach another.

This theorem thus underscores the practical dilemmas in fair machine learning
775 models. Achieving comprehensive fairness in ML systems often requires navigating complex trade-offs, necessitating a thoughtful prioritization of fairness criteria tailored to the specific context and ethical considerations of each use case. The Impossibility Theorem serves as a critical reminder of the limitations and careful considerations required in the pursuit of fair decision making systems, highlighting
780 the importance of making informed, contextually sensitive decisions when implementing fairness metrics.

2.3 Fair classification

In this section, we review pertinent literature on fair machine learning, placing a particular emphasis on in-processing techniques. Fairness intervention methods can
785 be classified into three categories based on the stage at which they occur, as proposed by MEHRABI *et al.* (2021) and ALER TUBELLA *et al.* (2022):

Pre-processing intervene before learning, modifying the data to reduce existing biases;

In-processing intervene during learning by modifying the objective functions or
790 imposing constraints to the model in order to mitigate discriminatory effects;

Post-processing affects predictions produced by the model after learning to change possibly unfair outcomes.

One notable pre-processing method is the reweighting approach proposed by KAMIRAN e CALDERS (2012), which adjusts the weights of different samples in

795 the training data to ensure that underrepresented groups are fairly represented during training. Another significant pre-processing technique is the Fair Representation Learning by ZEMEL *et al.* (2013), which learns a latent representation of the data that obfuscates sensitive attributes while retaining the information necessary for accurate predictions. An example of a post-processing method is the Reject Option
800 Classification by KAMIRAN *et al.* (2012), which changes the decisions of the classifier for individuals near the decision boundary. Another example is Equalized Odds and Equal Opportunity post-processing technique by HARDT *et al.* (2016), which adjusts the classifier’s predictions to equalize the true positive and false positive rates across different demographic groups.

805 In this work, we incorporate information about disparities among social groups in the dataset into our model by modifying the loss function through the use of a transition matrix. This fairness intervention is thus classified as an in-processing technique. Other relevant in-processing strategies for fair classification include Naive Bayes approaches for discrimination-free classification (CALDERS e VER-
810 WER, 2010), Fairness Through Awareness Framework (DWORK *et al.*, 2012), Fairness-Aware Classifier with Prejudice Remover Regularizer KAMISHIMA *et al.* (2012), α -discriminatory empirical risk minimizer (WOODWORTH *et al.*, 2017), Disparate Impact and Disparate Mistreatment frameworks for margin-based classifiers (ZAFAR *et al.*, 2017a,b), Weak Agnostic Learning to Auditing Subgroup Fair-
815 ness (KEARNS *et al.*, 2019, 2018), One-Network Adversarial Fairness (ADEL *et al.*, 2019), FairGan⁺ (XU *et al.*, 2019), Monte Carlo policy gradient method (PETROVIĆ *et al.*, 2021), Fairness-accuracy Pareto (WEI e NIETHAMMER, 2022), and Pareto front stochastic multi-gradient (LIU e VICENTE, 2022) based in original stochastic multi-gradient (MERCIER *et al.*, 2018) to Multi-Objective Optimization
820 and the hybrid Adaptive Priority Reweighting approach HU *et al.* (2023).

In KAMISHIMA *et al.* (2012) the authors proposes the Prejudice Remover (PR) which is a regularizer to logistic regression models. It introduces an additional term in the loss function to penalize the model for making decisions based on sensitive features. The objective function to be minimized is available on Equation 2.5,
825 where Θ is the model parameters, $L(D; \Theta)$ the log-likelihood, $R(D, \Theta)$ the prejudice remover regularizer, η a regularization parameter controlling the trade-off between fairness and accuracy, and λ a parameter for the L2 regularizer.

$$-L(D; \Theta) + \eta R(D, \Theta) + \frac{\lambda}{2} \|\Theta\|^2 \quad (2.5)$$

The regularizer $R(D, \Theta)$ aims to minimize the mutual information between the predicted outcomes and the sensitive features, thereby reducing the model’s reliance
830 on sensitive information. The mutual information is approximated using sample

means to make the computation feasible for large datasets. The authors compared the proposed method with Calders-Verwer 2-naïve-Bayes method (CALDERS e VERWER, 2010), showing that the PR effectively reduced bias, though sometimes at the cost of decreased accuracy.

As an alternative to mitigating unwanted bias, ZHANG *et al.* (2018) proposes an adversarial method for reducing bias in machine learning models, namely Adversarial Debiasing (AD). This technique involves training a neural network predictor to forecast an outcome variable from inputs while an adversary network simultaneously attempts to predict a sensitive attribute, which should not influence the outcome.

The method utilizes an adversarial network architecture where the main predictor’s task is complemented by an adversarial model that tries to learn the sensitive attribute. By integrating the adversarial model’s feedback into the training process, the predictor learns to make decisions that are increasingly independent of the sensitive attribute. This setup allows the model to attain to fairness constraints like Statistical Parity (Definition 13), Equal Opportunity (Definition 14), and Equalized Odds (Definition 16).

In a similar vein, KEARNS *et al.* (2018) propose a framework for ensuring subgroup fairness, addressing the issue of fairness gerrymandering. Below, a toy example given by the authors illustrating a scenario where the referred fairness gerrymandering occurs.

Imagine a setting with two binary features, corresponding to race (say black and white) and gender (say male and female), both of which are distributed independently and uniformly at random in a population. Consider a classifier that labels an example positive if and only if it corresponds to a black man, or a white woman. Then the classifier will appear to be equitable when one considers either protected attribute alone, in the sense that it labels both men and women as positive 50% of the time, and labels both black and white individuals as positive 50% of the time. But if one looks at any conjunction of the two attributes (such as black women), then it is apparent that the classifier maximally violates the statistical parity fairness constraint. Similarly, if examples have a binary label that is also distributed uniformly at random, and independently from the features, the classifier will satisfy equal opportunity fairness with respect to either protected attribute alone, even though it maximally violates it with respect to conjunctions of two attributes.

Their approach involves defining fairness for exponentially or infinitely many subgroups defined by a structured class of functions over the protected attributes, not only for a small number of pre-defined groups as considered in hegemonic fair

classification approaches. This framework is formalized as a two-player zero-sum
870 game between a Learner (the primal player) and an Auditor (the dual player), where
the Learner aims to minimize classification error while the Auditor seeks to identify
and penalize fairness violations. The computational challenges of this approach
are mitigated by connecting it to weak agnostic learning, which allows the use of
practical machine learning heuristics for effective auditing and learning in real-world
875 applications.

The algorithms derived from this framework provably converge to the best fair
distribution over classifiers, given access to oracles capable of optimally solving the
agnostic learning problem. These algorithms include a variant based on the no-regret
Follow the Perturbed Leader algorithm and another using Fictitious Play, both of
880 which have been implemented and evaluated on real datasets, demonstrating their
efficacy in achieving subgroup fairness.

The Adaptive Priority Reweighting HU *et al.* (2023) method introduces a sys-
tematic approach to increase fairness and generalizability of classifiers by dynami-
cally adjusting sample weights based on their proximity to the decision boundary.
885 Initially, the training samples are divided into subgroups according to their sen-
sitive attributes and classifier predictions. Each sample’s distance to the decision
boundary is then computed and updated iteratively. During each iteration, sub-
group weights are recalibrated by comparing the observed probability of the positive
prediction rate within each subgroup to the expected probability under statistical
890 independence. This comparison helps to assign higher weights to samples closer
to the decision boundary, thereby prioritizing them in the training process. The
weighted loss function is optimized using a stochastic gradient descent algorithm,
which iteratively adjusts the classifier to reduce bias while maintaining accuracy. By
continuously updating the weights and distances, the Adaptive Priority Reweighting
895 method ensures that the classifier learns to make fairer decisions that generalize well
to unseen data, addressing the limitations of traditional reweighing methods that
often fail to generalize beyond the training set.

The method is evaluated on benchmark datasets, outperforming many state-of-
art pre-processing, in-processing and post-processing fair classification techniques,
900 promoting fairness on both finetuned pre-trained models and newly trained models.
This technique can be classified as a hybrid approach, performing the traditional
pre-processing instance reweighing through an adaptive training algorithm.

Recently, special attention has been given in fair machine learning research top-
ics like addressing multiple sensitive attributes or multiple classes D’ALOISIO *et al.*
905 (2023); LIU *et al.* (2023), loss balancing techniques KIM *et al.* (2023); KHALILI
et al. (2023), where the objective is to balance the loss across different groups in-
stead of predictive metrics, adversarial approaches MA *et al.* (2023); GRARI *et al.*

(2023); LIANG *et al.* (2023); ZHANG *et al.* (2023a); MOUSAVI *et al.* (2023); WEI
et al. (2023) and the privacy concerns involving fairness under federated learning
910 settings CHEN *et al.* (2024); VUCINICH e ZHU (2023). Another relevant research
topic in fair machine learning is learning under censored data ZHANG e WEISS
(2022); ZHANG *et al.* (2023b); ZHANG e WEISS (2023); ZHANG *et al.* (2023c),
which we will discuss in section ??.

Chapter 3

915 Fair loss function from noise robustness

In this chapter we propose a novel loss function inspired by label noise robustness methods to fair classification problems. The core of this proposal consists in using transition matrices as parameters to a proper loss correction PATRINI *et al.* (2017),
920 with matrices values as factors to redistribute unbalanced bias across different groups within the sensitive feature.

3.1 Preliminaries

The presence of noise in data can substantially decrease model performance in classification problems. Noise can be defined as non systematic errors that obscures the
925 relationship between features of an instance and its class (FRÉNAY e VERLEYSEN, 2014; HICKEY, 1996; QUINLAN, 1986). Two types of noise are found in literature, in features (or attributes) and in labels (or classes). Feature noise affects observed values, e.g. by adding a small Gaussian noise on each feature during measurement. Likewise, label noise change the observed label assigned to an instance, e.g. by
930 randomly inverting labels in a binary classification problem. Although feature noise could affect model performance, label noise is potentially more harmful, since we frequently have many features and only one label. Note that in label noise only the observed label of an instance is affected, its true class remains the same.

The label noise taxonomy considers three types of noise: Noisy Completely at
935 Random, Noisy at Random, and Noisy Not at Random (FRÉNAY e VERLEYSEN, 2014). Figure 3.1 presents the statistical dependency between features X , class Y , observed label \tilde{Y} and the occurrence of error E , i.e. $E = 1$ when $Y \neq \tilde{Y}$. The simplest type is Noisy Completely at Random, where the occurrence of error E not depend on X and Y , e.g. randomly flipping labels on a binary classification problem.

940 In Noisy at Random, the occurrence of error E depends only on Y , e.g. randomly flipping labels on binary classification with different rates for positives and negatives classes. Noisy Not at Random considers the occurrence of error E depending on both Y and X , e.g. flipping labels on binary classification with different rates for each group of instances of a certain feature.

Figure 3.1: Noise taxonomy from a statistical perspective. (a) completely random noise (NCAR), (b) random noise (NAR) and (c) non-random noise (NNAR). The arrows correspond to the statistical dependencies. For clarity, the dependency between X and Y was placed as a dashed arrow.

945 Many label noise robustness methods can be found on literature, in this work we highlight the *backward* and *forward* loss corrections, proposed by PATRINI *et al.* (2017) using concepts of loss factorization (PATRINI *et al.*, 2016). Those loss correction techniques considers a NAR label noise, which is described by a transition matrix T such as

$$T_{i,j} = P(\tilde{Y} = y_j | Y = y_i), \quad (3.1)$$

950 where $\mathcal{Y} = \{y_1, y_2, \dots, y_c\}$ is the set of all possible class labels. Transition matrix includes corruption probabilities for every possible label combination, each value represents the probability of one label be corrupted onto another. This matrix is row-stochastic and not necessarily symmetric across the classes.

$$\ell^{\leftarrow}(P(\tilde{Y}|X)) = T^{-1}\ell(P(\tilde{Y}|X)) \quad (3.2)$$

The backward loss correction is defined by Equation 3.2 to an arbitrary loss
 955 function ℓ and a transition matrix T . The backward loss correction involves a linear combination of the loss values for each observed label, using coefficients that depends on the probability that each observed label reflects the true class. Intuitively, we are reweighting the loss according to the noise probabilities of each label using the inverse of T and thus somehow going one step back, reverting the noise
 960 effects. This corrected loss is unbiased and can be minimized with any conventional back-propagation algorithm, making it flexible to include within different training techniques and data pipelines.

$$\ell^{\rightarrow}(P(\tilde{Y}|X)) = \ell(T^{\top}P(\tilde{Y}|X)) \quad (3.3)$$

However, backward correction requires matrix inversion, which may not exist or may lead to numerical instabilities if the transition matrix T is ill-conditioned. Although there is possible solutions to a bad condition number of T , one should consider using the forward correction, a backward variation proposed by PATRINI *et al.* (2017) to avoid this issue, as defined in Equation 3.3. While backward acts on the loss itself, forward corrects model predictions. Forward correction does not have the same theoretical guarantees as backward, but offers a label noise robustness, ensuring that the learned model is the minimize over the clean distribution without the need of matrix inversion.

Now we discuss classification methodologies that operate in the presence of label noise. While our research does not directly tackle fairness problems in the presence of label noise, we highlight relevant works that, akin to ours, bridge the domains of fairness and noise in machine learning research.

Some recent works deal with fairness problems in the presence of noise. For example, the sensitive attribute available could be noisy, which could distort the effects of fairness intervention. In this context, LAMY *et al.* (2019) uses noise-rate estimators from the label noise literature to change a fairness model. Also, FOGLIATO *et al.* (2020) proposes a framework for assessing how assumptions on the noise across groups affect the predictive bias properties in risk assessment models. Furthermore, WANG *et al.* (2020) considers the consequences of naively relying on noisy protected group labels while proposing two new optimization approaches with sensitive attribute noise robustness. A denoised version of the selection problem to deal with noisy sensitive attributes is proposed in MEHROTRA e CELIS (2021). Lastly, CELIS *et al.* (2021) proposes an optimization framework for classification in the presence of noisy protected attributes.

There is also the perspective of dealing with the proxy features divergence or covariance. A theoretical approach to this issue identifying potential sources of errors can be found in PROST *et al.* (2021). The problem of measuring group fairness in ranking based on divergence with proxy features is investigated by GHAZIMATIN *et al.* (2022). A framework of fair semi-supervised learning in the pre-processing phase can be found in ZHANG *et al.* (2022), which includes predicting labels for unlabeled data, a resampling method, and ensemble learning to improve accuracy and decrease discrimination.

Another research direction is considering how fair models perform in the presence of NNAR label noise, where error rates of corruption depend both on the label class and the membership of a protected subgroup. In this scenario WANG *et al.* (2021) addresses the problem of fair classification and WU *et al.* (2022) provides a general framework for rewriting the classification risk and the fairness metric in terms of noisy data and thereby building robust classifiers. In GHOSH *et al.* (2023) a study

about the presence of noise in the protected attribute can be found.

Furthermore, many recent works deal with fairness under semi-supervised settings considering censored data, that is, for some individuals the class label is not available due to censorship ZHANG e WEISS (2022); ZHANG *et al.* (2023b); ZHANG e WEISS (2023); ZHANG *et al.* (2023c). In this scenario, the main approach is to use some technique to estimate the missing data instead of removing the instance from training data. This is closely related to the previous problems of fair learning under noisy data. In censored fairness problems noise can be interpreted as a kind of censorship, as the original data affected by noise is not available.

Bias and noise are two related phenomena, both corrupt data affecting models trained with this data. For example, if noise disproportionately affects different groups this potentially produces unfairness in models that use this data in training (WANG *et al.*, 2021). For example, we could have positive true class ($Y = 1$) flipped into negative labels ($\tilde{Y} = 0$) more frequently in the protected group ($A = 1$) than in the privileged group ($A = 0$). Simultaneously, the negative class ($Y = 0$) could be more frequently flipped into positive observed labels ($\tilde{Y} = 1$) within the privileged/unprotected group ($A = 0$). This scenario could lead to a higher false negative rate for the protected group and a higher false positive rate for the privileged group. In this case the Noisy Not at Random data would be a source of negative social bias.

As referred to before, in MEHRABI *et al.* (2021) a non-exhaustive list of bias types was presented. In the scenario described above, the incorrect measurement of the true class resulted in a different observed label ($Y \neq \tilde{Y}$), which could be classified as a *Measurement Bias*. Similarly, a Noisy Not at Random data could lead to a *Population Bias*, where the characteristics of the population represented in the data differ from those of the original target population.

It can be challenging to distinguish between label noise and bias in certain scenarios, specially when noise disproportionately affects different social groups. Although there is some overlapping, they are distinct phenomena. Label noise is a stochastic process that is considered independent and unintentional (FRÉNEY e VERLEYSEN, 2014), whereas bias is rooted in historical and social issues and could be intentional. Furthermore, even noise-free data, correctly represented by observed features and labels, may be unfair since the social phenomena that produce this data could be biased against some groups.

Previous studies on fair machine learning have largely concentrated on understanding how noisy or censored data affects fair learning and on mitigating these effects. Thus, the objective of this work is not to theoretically deal with fair machine learning as a label noise problem or incorporate noisy classes or attributes in fairness problems. In contrast, our approach is inspired by label noise techniques, but with

a distinct goal: not merely to analyze or mitigate the impact of noise or censorship, but to directly address and reduce unfairness itself.

To achieve a competitive trade-off between performance and fairness in the proposed method, we discuss multi-objective optimization within the context of fair machine learning. A model that substantially decreases model performance to reduce unfairness may not be a viable option, as low performance could harm all groups affected by the model’s decisions, including protected groups. Similarly, a model projected to be a fair alternative that keeps performance almost intact, but with little or even no gain in fairness, is not practically relevant. It is possible that fine-tuning this trade-off could result in a fairer solution that achieves better performance than traditional methods, but this is not the case for most practical problems. Achieving this balance is one of the most challenging tasks in fair machine learning.

In this context, an interesting approach is to deal with fair machine learning as a Multi-Objective Optimization (MOO) problem, where predictive performance and fairness metric are the objectives, which could be defined according Equation 3.4, where λ is a parameter configuration in the space Λ , $\rho : \Lambda \mapsto [0, 1]$ is a model performance metric and $\varphi : \Lambda \mapsto [0, 1]$ a fairness metric. The set of all optimal solutions is called Pareto front, where one objective cannot be improved without sacrificing another. In this setting there is no single λ^* optimal solution, but a set of solutions forming a Pareto front (PARETO, 1906).

$$\begin{aligned} & \max (\rho(\lambda), \varphi(\lambda)) \\ & \text{subject to } \lambda \in \Lambda \end{aligned} \tag{3.4}$$

One of the most frequent approach to deal with MOO problems like these is to combine the multiple function outputs to a single scalar, which is called scalarization. Therefore, we could describe a general scalarization setup to Equation 3.4 according Equation 3.5. The effectiveness of this approach is that is also possible to use single objective optimization techniques to tackle the MOO optimization problem. In this scenario a relevant issue is to select a scalarization setup capable of promote a proper trade-off of all the objectives thorough the optimization process given the optimization method.

$$\arg \max_{\lambda \in \Lambda} G(\lambda) = (\rho(\lambda), \varphi(\lambda)) \tag{3.5}$$

The fairness-accuracy Pareto front is formally described in WEI e NIETHAMMER (2022), which demonstrate that many existing fairness methods are performing a linear scalarization scheme and argues that it has several limitations in recovering Pareto optimal solutions. Instead, authors proposes a Chebyshev scalarization

scheme, that is theoretically superior than linear scheme. A characterization of the accuracy-fairness trade-off as a Pareto front can be found in LIU e VICENTE (2022).
1075 Also, MERCIER *et al.* (2018) proposes a stochastic multi-gradient based in original stochastic multi-gradient to Multi-Objective Optimization.

Another remarkable use of MOO in Fair Machine Learning is to perform a Fair Hyperparameter Optimization, which provides a model agnostic approach with flexibility to apply in multiple machine learning pipelines. A time-efficient Bayesian
1080 Optimization approach can be found in SCHMUCKER *et al.* (2020), combining scalarization techniques with the bandit-inspired Hyperband (LI *et al.*, 2017) algorithm to Hyperparameter Optimization in context of fairness.

A general objective function to be used with some popular off-the-shelf hyperparameters optimization techniques combining model performance and fairness in
1085 a flexible setting can be found in F.CRUZ *et al.* (2021). The authors argues that in fairness context the Pareto front is most often convex, thus proposes a simple scalarizing function that could be applied to reduce G to a single scalar with weighed l_p -norm. Also, they argue that GIAGKIOZIS e FLEMING (2015) demonstrate the use of l_p -norms with a high p value leads to slower convergence. Thus,
1090 the optimization metric $g(\lambda) = \|G(\lambda)\|_1$ is optimized according Equation 3.6, where α is the relative importance of predictive performance and fairness and λ is a parameter configuration in the space Λ . In experiments, α is fixed at 0.5, giving same importance to both objectives.

$$G(\lambda) = \alpha \cdot \rho(\lambda) + (1 - \alpha) \cdot \varphi(\lambda) \quad (3.6)$$

A Multi-objective SVMOptimizer with Dataset Constraints is proposed by GOH
1095 *et al.* (2016), where the objective is to minimize multiple objectives on real-world datasets, such as misclassification error and positive prediction at specific rate to some population. A custom reinforcement learning algorithm directly modeling performance and fairness as objectives is proposed by PETROVIĆ *et al.* (2021). Authors proposes using as reward function the difference between model performance
1100 (Area Under the ROC Curve) and three different fairness metrics (Statistical Parity, Equal Opportunity and Equalized Odds), each one with its respective importance coefficient. In experimental setups only one of those coefficient are different from zero. Thus, the optimized metric could be written as $G(\lambda) = \rho(\lambda) - \alpha \cdot \varphi(\lambda)$, where α is the relative importance of fairness.

1105 3.2 Fair Transition Loss

We propose a novel fair classification method inspired by techniques used for classification in the presence of label noise. By using some features of label noise methods that redistribute probabilities for unbalanced noise across classes, our approach reweights prediction probabilities to reduce disparities in favorable and unfavorable outcomes across social groups. This proposal was originally inspired by BRAIDA (2018), that applies label noise techniques in order to achieve label noise robust collaborative filtering,

Whereas forward loss correction (PATRINI *et al.*, 2017) uses a transition matrix with corruption probabilities for every label combination in the case of NAR, fair classification problems are more related to NNAR. While forward loss correction uses a transition matrix with corruption probabilities for each label combination, as in the case of NAR, fair classification problems align more with NNAR scenarios. In NNAR, the probability of corruption depends not only on the true class but also on features, analogous to how bias in fairness problems is directed against certain groups. Here our correction does not revert a random label corruption from the true class, but a potentially unfair prediction. While noise label techniques, like forward (PATRINI *et al.*, 2017), aims to correct the prediction targeting a unknown true class using the available noisy label, analogously the proposed technique focus on correcting predictions chasing the unknown fair class using the available unfair label. Despite those are distinct phenomena, the corrections works the same way, adjusting the probabilities of predictions produced by a machine learning model during the training.

Thus, our proposal is a prediction probability loss reweighting technique that accounts different rates to each group of the sensitive feature, instead of using the same correction to every individual. A correction method that incorporates different probabilities for protected and unprotected groups could be more effective in mitigating bias during the learning phase. Specifically, we want a forward-based correction that takes into account a different matrix to each group of sensitive features, not only one transition matrix as used in label noise techniques. In this scenario, each group of sensitive feature have its own correction, with its own rates for each class combination. Ideally, if we can find an appropriate transition matrix that describes the bias to each group in a specific problem, we can apply a correction that attenuates those negative effects by reweighting model’s predictions in the learning process.

Next, we formally present Fair Transition Loss. For purpose of clarity we follow the same structure available at (PATRINI *et al.*, 2017), with the pertinent changes to our scope. The Fairness Transition Matrix T_a is defined with some abuse of

notation to the group $A = a$ of the sensitive feature as

$$T_{a,i,j} = P(\tilde{Y} = y_j | Y = y_i, A = a), \quad (3.7)$$

where label space $\mathcal{Y} = \{y_1, y_2, \dots, y_c\}$, c the number of classes, $Y = y_i$ is the
 1145 unknown fair class and $\tilde{Y} = y_j$ is the available and possibly unfair label. Here, $T_{a,i,j}$ is the probability of the fair class $Y = y_i$ being unfairly labeled as $\tilde{Y} = y_j$ to an individual of the group $A = a$ due negative social bias. Therefore, suppose that there is an invertible link function $\psi : \Delta^{c-1} \rightarrow \mathbb{R}^c$, where $\Delta^{c-1} \subset [0, 1]^c$ is the c -simplex, the simplex in a c -dimensional space. Thus, a composite loss function,
 1150 denoted by $\ell_\psi : \mathcal{Y} \times \mathbb{R}^c \rightarrow \mathbb{R}$ if it can be written as a decomposition of ψ^{-1} , that is,

$$\ell_\psi(Y, h(X)) = \ell(Y, \psi^{-1}(h(X))), \quad (3.8)$$

where $h : \mathcal{X} \rightarrow \mathbb{R}^c$ is a standard artificial neural network with multiple layers using activation functions, and $h(X)$ is the output of this neural network to a given input X . For example, to cross entropy loss function the softmax is the inverse link function. Proper loss functions are those that can be directly used to estimate class
 1155 probabilities. The minimizer of a proper composite loss has the particular form of the link function applied to the conditional class probabilities $P(Y|X)$. Adding a new conditioning to this formulation, to an individual from group $A = a$ we have

$$\arg \min_h \mathbb{E}_{X,Y} \ell_\psi(Y, h(X|A = a)) = \psi(P(Y|X, A = a)). \quad (3.9)$$

Fair Transition Loss consists in correcting model's predictions with the same technique as forward, but taking into account the sensitive attribute value when
 1160 choosing the transition matrix. In Theorem 1 the Fair Transition Loss is formally defined, with a guarantee about its minimizers.

Theorem 1. *Suppose that the Fairness Transition Matrix T_a for a given sensitive attribute $A = a$ is non-singular. Given a proper composite loss ℓ_ψ , define the Fair Transition Loss as*

$$\text{FTL}_\psi(h(X|A = a)) = \ell(T_a^\top \psi^{-1}(h(X|A = a))).$$

1165 *Then, the minimizer of the corrected loss under the unfair distribution is the same as the minimizer of the original loss under the fair distribution:*

$$\arg \min_h \mathbb{E}_{X,\tilde{Y}} \text{FTL}_\psi(Y, h(X|A = a)) = \arg \min_h \mathbb{E}_{X,Y} \ell_\psi(Y, h(X|A = a)).$$

Proof. First notice that:

$$\begin{aligned}\text{FTL}_\psi(Y, h(X|A=a)) &= \ell(Y, T_a^\top \psi^{-1}(h(X|A=a))) \\ &= \ell_\phi(Y, h(X|A=a)),\end{aligned}\tag{3.10}$$

where we denote $\phi^{-1} = \psi^{-1} \circ T_a^\top$. Equivalently, $\phi = (T_a^{-1})^\top \circ \psi$ is invertible by composition of invertible functions, its domain is Δ^{c-1} as of ψ and its codomain is \mathbb{R}^c . The last loss in Equation 3.10 is proper composite with link ϕ . Finally, from
1170 Equation 3.9, the loss minimizer over the unfair distribution is

$$\arg \min_h \mathbb{E}_{X, \tilde{Y}} \ell_\phi(Y, h(X|A=a)) = \phi(P(\tilde{Y}|X, A=a))\tag{3.11}$$

$$= \psi((T_a^{-1})^\top) P(\tilde{Y}|X, A=a)\tag{3.12}$$

$$= \psi(P(Y|X, A=a)),\tag{3.13}$$

that proves the Theorem by Equation 3.9 once again. \square

Considering a common scenario with only two groups in sensitive attributes (protected and privileged), we can correct the model's predictions using two different
1175 fair transition matrices. One with rates applied while learning instances from the protected group, and the other with rates applied while learning instances from the privileged group. Formally, to the sensitive feature $A \in \{0, 1\}$, let T_0 the transition matrix associated with privileged/unprotected group ($A = 0$) and T_1 with the protected group ($A = 1$), FTL can be computed as

$$\text{FTL}(P(\tilde{Y}|X)) = (1-A) \cdot \ell(T_0^\top P(\tilde{Y}|X)) + A \cdot \ell(T_1^\top P(\tilde{Y}|X)),\tag{3.14}$$

1180 which in a standard batch learning, consists in alternating the transition matrix applied according instance's sensitive attribute.

Furthermore, to a common binary classification problem, where there is a positive (favorable) class and a negative (unfavorable) class, and two groups from sensitive feature (protected and privileged), we have two 2×2 transition matrices. Intuitively
1185 we are choosing rates to increase or decrease the probability of each group to be classified with the positive or negative prediction. We name those rates associated with increasing the probability to achieve the positive outcome as *promotion* rate, and those associated with increasing the probability to receive the negative outcome as *demotion* rate. As the transition matrix is row-stochastic, we can describe T_0 and
1190 T_1 as

$$T_0 = \begin{bmatrix} 1-d_0 & d_0 \\ p_0 & 1-p_0 \end{bmatrix}, \quad T_1 = \begin{bmatrix} 1-d_1 & d_1 \\ p_1 & 1-p_1 \end{bmatrix},\tag{3.15}$$

where d_0 is the privileged demotion rate, p_0 the privileged promotion rate, the d_1 protected demotion rate, and p_1 the protected promotion rate. With an appropriate combination of d_0 , p_0 , d_1 , p_1 we can define a transition matrix pair that should be able to reweight model’s predictions with *FTL* to achieve fairer results with a reasonable model performance. The central problem in our methodology thus relies in choosing these rates, which can be seen as an hyperparameter optimization problem.

Our hyperparameter optimization problem consists in finding an optimal trade-off between fairness and performance, which can be described as a MOO problem, as defined in Equation 3.4. Here, the hyperparameter configuration is $\lambda = (d_0, p_0, d_1, p_1)$. Since the transition matrix is row stochastic these parameters are sufficient to define T_0 and T_1 . We want to maximize model performance $\rho(\lambda)$ and minimize fairness metric $\varphi(\lambda)$.

$$G(\lambda) = \rho(\lambda) - \varphi(\lambda). \quad (3.16)$$

Following some MOO approaches to fair machine learning, we will use a linear scalarization setup to define the optimization metric (PETROVIĆ *et al.*, 2021; SCHMUCKER *et al.*, 2020). As we yet have four hyperparameter to fine-tune, and in F.CRUZ *et al.* (2021) the relative importance α is fixed at 0.5, we choose a simple and intuitive objective function in Equation 3.16 to maximize without the parameter α , i.e., giving same importance to fairness and performance. In Equation 3.16 we establish a simple objective to optimize, but one might need to consider a different formulation depending on the specific problem at hand.

3.3 Experimental setup

In this section, we detail the experimental setup employed to benchmark our model against relevant in-processing fair classification models found in standard fairness toolkits, namely, Prejudice Remover (KAMISHIMA *et al.*, 2012), Adversarial Debiasing (ZHANG *et al.*, 2018), and Gerry Fair Classifier (KEARNS *et al.*, 2018). We use the implementation of these methods from AI Fairness 360 toolkit (BELLAMY *et al.*, 2018). The baseline is a Standard MLP using two hidden layers with 100 hidden units each, *ReLU* activation function, batch size of 64, 50 epochs early stopped at 3 epochs without improvement (LI *et al.*, 2020) and softmax in output, trained with ADAM optimizer (KINGMA e BA, 2015) with learning rate at $3e-4$. The only difference between baseline MLP and Fair Transition Loss MLP is that baseline uses standard Binary Cross Entropy Loss. The Gerry Fair Classifier implementation uses the False Negative Rate as its fairness definition and in Adver-

1225 serial Debiasing classifier the hidden size is 100 units. Additionally, we compare the Fair Transition Loss within the Adaptive Priority Reweighting HU *et al.* (2023), a promising fairness promoting technique focused on improving generalization, which outperformed many recent methods such as JIANG e NACHUM (2020), MROUEH *et al.* (2021), and ROH *et al.* (2021).

1230 Our methodology consists of two phases: hyperparameter tuning and testing. In the hyperparameter tuning phase we perform a Bandit-Based pruning approach using HyperBand (LI *et al.*, 2018) with Tree-structured Parzen Estimator Sampler (TPE) (BERGSTRA *et al.*, 2011) over 100 trials. Those techniques achieves better solutions to multi-objective hyperparameter optimization in the same number of tri-
1235 als than conventional approaches like Grid Search and Random Search (MORALES-HERNÁNDEZ *et al.*, 2023). At each trial fitness function is evaluated by performing a complete training and validation, where both model performance and fairness metrics are assessed. The fitness function is computed based on the objective defined in Equation 3.16. This same experimental procedure can be adapted to utilize other
1240 hyperparameter tuning algorithms such as FairRandom Search, Fair TPE, and Fairband (F.CRUZ *et al.*, 2021).

Once the best hyperparameters are selected, we proceed to the testing phase, where a new training is conducted using those optimal hyperparameters. After this training, we evaluate the model’s performance on a separate test set that was not
1245 used during the hyperparameter tuning phase, which are reported. This complete tuning-training-testing described is repeated 15 times with dataset re-sampling then we proceed to comparison. Here the re-sampling consists in shuffling the whole dataset before splitting, which is better described further in this section.

As the objective defined in Equation 3.16 can be achieved with different perfor-
1250 mance and fairness metrics, we compare the proposed method with other relevant in-processing techniques from literature in different optimization scenarios. In addition to Accuracy (Acc.) as performance metric, we also evaluate the Mathews Correlation Coefficient (MCC), which has advantages over F1 score and Accuracy in binary classification evaluation (CHICCO e JURMAN, 2020). To this performance metric,
1255 1 means a perfect prediction according true class, -1 a complete inversion and 0 an average random outcome. As fairness metric we consider Statistical Parity (Stat. Parity, Definition 13), Equal Opportunity (Eq. Opp., Definition 14) and Equalized Odds (Eq. Odds, Definition 16). Thus we have the following optimization scenarios: MCC and Statistical Parity; MCC and Equal Opportunity; MCC and Equalized
1260 Odds; Accuracy and Statistical Parity; Accuracy and Equal Opportunity; Accuracy and Equalized Odds.

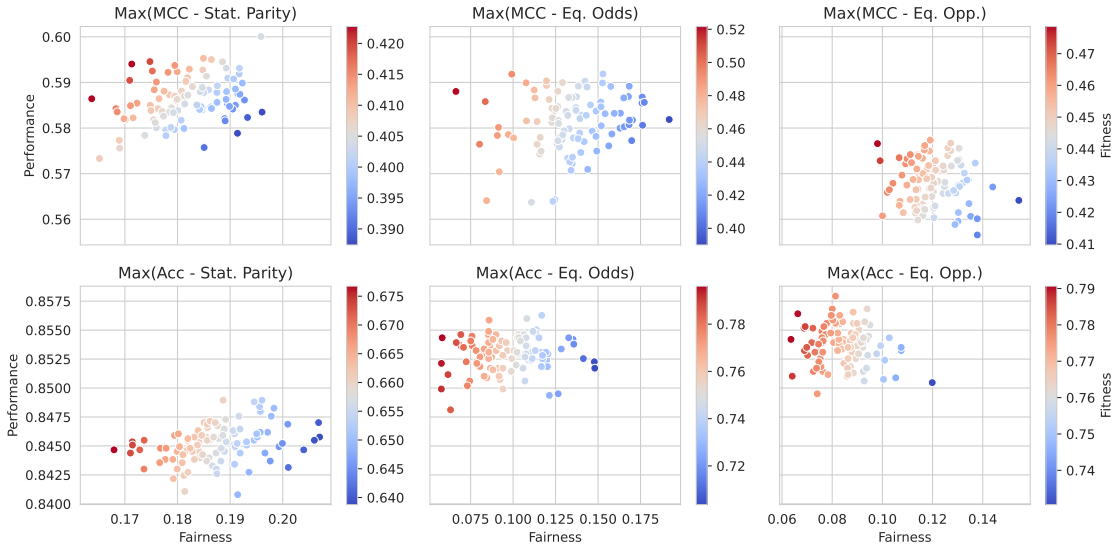

Table 3.1 presents the methods hyperparameters along with their corresponding search ranges or options. While each method may possess a varying number of

Table 3.1: Hyperparameters search ranges or options of each method.

Method	Parameter	Range/options
Standard MLP (baseline)	dropout	[0.0, 0.2]
Prejudice Remover (KAMISHIMA <i>et al.</i> , 2012)	η	[0.0, 50.0]
Adversarial Debasing (ZHANG <i>et al.</i> , 2018)	α	[0.0, 1.0]
Gerry Fair Classifier (KEARNS <i>et al.</i> , 2018)	C	[0.0, 20.0]
	γ	{0.1, 0.01, 0.001}
Adaptive Priority Reweighting (HU <i>et al.</i> , 2023)	α	[0.0, 10000.0]
	η	[0.5, 3.0]
Fair Transition Loss	d_0, p_0, d_1, p_1	[0.0, 1.0]
	dropout	[0.0, 0.2]

hyperparameters and range sizes, all are optimized under the same conditions and number of configurations to guarantee a balanced comparison. In Figure 3.2 we present a brief sensibility analysis on the fitness functions with different fairness and performance values over those six optimization scenarios listed before. Here we perform a complete hyperparameter tuning with HyperBand and TPE over 100 trials using the baseline model (Standard MLP) with the Adult Income dataset optimizing the hyperparamers reported on Table 3.1. This sensibility analysis aims better present the linear objective function behavior within performance and fairness metrics evaluated in this study.

Figure 3.2: Sensibility analysis on optimized fitness functions within different performance and fairness metrics. Results from complete hyperparameter tuning through 100 trials with baseline model over the Adult Income dataset.

Each plot in Figure 3.2 illustrates the fitness value corresponding to specific performance and fairness metrics. The color scheme in the plots represents the fitness values, with higher values in red and lower values in blue. On the x -axis, we

have the fairness metric, where a lower value is preferable. The y -axis represents the performance metric, with higher values being preferred. The color gradient in these plots demonstrates the linear relationship between fitness and variations in the corresponding performance and fairness metrics. It is important to note that the scale of the fairness metric is significantly smaller than that of the performance metric. However, it is sufficiently to act as a penalization. The general fitness function in the scenarios described is capable of producing results with reduced bias while maintaining similar performance levels. Although each metric combination has different scales, each hyperparameter tuning experiment uses only one metric combination at a time, ensuring consistency in the optimization process.

On these plots we used the fitness and performance levels obtained through the TPE sampler with HyperBand pruning during the hyperparameter tuning phase using the baseline model, as previously described. In this setting, the solution (i.e., the combination of hyperparameters) that yields the best fitness value is selected for a new complete training phase. This involves assessing metrics on test data not used in the previous phase. To ensure robust evaluation, the dataset is reshuffled, re-split into train, validation and test segments, and this entire process is repeated over 15 iterations.

To properly compare this set of 15 results of each method, we conduct an Almost Stochastic Order (ASO) test (DROR *et al.*, 2019), which is a significance test suitable for comparing complex machine learning models with various hyperparameters. The ASO test involves evaluating a set of metrics through multiple samplings of a Collection of Statistics (in this case assessed in test phase using random resampling) to compare one method against another. The $ASO(A, B)$ function yields a value in the range $[0, 1]$, given two methods A and B . If $ASO(A, B)$ is lesser than 0.5, we can reject the null hypothesis and conclude that method A outperforms method B in the given task. That is, method A produces stochastically larger values than method B for a given metric. The lower the $ASO(A, B)$ value, the stronger the evidence that A is superior to B in that particular task, which can be interpreted as a confidence interval. Therefore, we perform pairwise comparisons between all methods for each optimization scenario outlined previously and for each dataset.

Our experiments uses common datasets used in Fair Classification problems, namely *Adult Income* (BECKER e KOHAVI, 1996), *German Credit* (HOFMANN, 1994), *Bank Marketing* (S. MORO e CORTEZ, 2012), and *COMPAS Recidivism* (JEFF LARSON e ANGWIN, 2016). We use the dataset readers available in the AI Fairness 360 toolkit (BELLAMY *et al.*, 2018) with its standard configurations. Instances with missing data are removed.

Table 3.2 present dataset details used in this work, including the number of features before pre-processing, the count of valid instances, the proportion of positive

Table 3.2: Dataset details used in this work, including performance and fairness metrics assessed to a standard classifier without tuning, and the maximum correlation between sensitive feature and the other features.

Dataset	Adult Income	Bank Marketing	COMPAS Recidivism	German Credit
# Features	102	57	401	58
# Instances	45222	30488	6167	1000
Sensitive Attribute	sex	age	race	sex
Positives	24.78%	12.66%	54.45%	70.00%
Negatives	75.22%	87.34%	45.55%	30.00%
Privileged	67.50%	97.17%	34.05%	69.00%
Unprivileged	32.50%	2.83%	65.95%	31.00%
Accuracy	0.846	0.906	0.358	0.685
MCC	0.572	0.553	-0.275	0.000
Stat. Parity.	0.192	0.106	0.172	0.074
Equal Opportunity	0.094	0.145	0.120	0.043
Equalized Odds	0.092	0.094	0.163	0.122
Maximum Correlation	0.527	0.364	0.826	0.593

and negative labels, the sensitive feature considered in experiments, the proportion of privileged and unprivileged groups within the corresponding sensitive feature, reference performance and fairness metrics using a standard Random Forest Classifier with 1000 classifiers without tuning, and the maximum correlation coefficient between the sensitive feature and the other features. The maximum correlation is useful to assess whether it is possible to use another feature as proxy to the sensitive feature, which is commonly referred as redlining effect (PEDRESCHI *et al.*, 2008).

The *Adult Income* dataset presents a classification task to predict whether an individual earns more than 50,000 per year. This dataset consists of 48,842 instances sourced from the U.S. 1994 Census database. The sensitive attribute used in this task is sex, with the male group considered privileged and the female group protected (unprivileged). In the *German Credit* dataset, the task consists of classifying 1,000 individuals described by a set of attributes as good or bad credit risks. Similar to the *Adult Income* dataset, here we use sex as the sensitive attribute, with the male group considered privileged and the female group protected. The *Bank Marketing* classification task aims to predict whether 45,211 clients will subscribe to a term deposit after direct marketing campaigns (phone calls) by a Portuguese banking institution. In this case, the sensitive feature is age, where individuals under the age of 25 are considered unprivileged, while those aged 25 and older are considered privileged. The *COMPAS* dataset presents around 80,000 criminal records from the Broward County Clerk’s Office. The task here is to predict whether a defendant will recidivate in the next two years. The sensitive feature in this case is race, with Caucasians as the privileged group and non-Caucasians (Black and Hispanic) as unprivileged.

For all datasets, the data preparation process is the same, one-hot encoding for categorical features and standardize the numerical features. We perform a random split, with 80% allocated for the hyperparameter tuning phase and the remaining 20% reserved for evaluating metrics in the test phase. Within the hyperparameter tuning phase, this corresponding fraction of data is further randomly split, with 80% assigned to training and 20% to validation. The validation set allows us to assess metrics and compute the fitness function for each hyperparameter configuration. In datasets where there is originally some kind of split (e.g., train set and test set in separate files), all available data is merged and then shuffled to produce new splits at each run.

3.4 Results and discussion

This section summarizes our results, comparing Fair Transition Loss (FTL) with the baseline Standard MLP (MLP) and some relevant fair in-processing methods: Adversarial Debiasing (AD), Prejudice Remover (PR), Gerry Fair Classifier (GFC) and Adaptive Priority Reweighting (APW).

As we have multiple optimization scenarios with different objective functions and datasets, and to each of them multiple runs, we present in Table 3.3 the results of the ASO test described before, which allow us to properly compare each method to FTL. Values under 0.5 (in bold) mean that we can reject the null hypothesis, i.e., FTL produces stochastically larger fitness than method in respective column for a objective and dataset. Lower values indicate stronger evidence. The complete results with mean and standard deviation of fitness, performance and fairness can be found in tables 3.5 to 3.10 to a fairness-performance trade-off analysis.

In 69 of 120 comparison scenarios from Almost Stochastic Order test (Table 3.3), it is possible to claim that FTL outperforms its competitor, i.e., FTL produces stochastically higher fitness values. Despite these positive results, one can argue that the proposed technique only adds extra hyperparameters that increase models flexibility to achieve higher fitness values. In other words, are we effectively describing bias in datasets by transition matrices as claimed before? To address this, we showcase various FTL hyperparameter combinations selected during the tuning phase described in Section 3.3, comparing with corresponding dataset information available at Table 3.2. We perform this analysis using *Adult Income* dataset. The corresponding hyperparameters can be found in Table 3.4. Here, high values mean that FTL alters the corresponding probabilities, while values close to zero indicate minimal interference by the method.

When optimizing for MCC and Statistical Parity, there’s a notable high value for protected promotion. This value is compatible with the high corresponding fair-

Table 3.3: Almost Stochastic Order test comparing Fair Transition Loss fitness. Values under 0.5 (in bold) mean that FTL outperforms corresponding method in such optimization scenario.

Fairness/Performance Metric	Dataset	MLP	AD	PR	GFC	APW

	German Credit	1.00	0.12	1.00	1.00	1.00

ness metric for this dataset, approximately 0.19 without correction. This increases the likelihood that an unprivileged instance receives a favorable outcome. Since statistical parity only compare the probability of a positive outcome across groups (ignoring true class) this is enough. The other hyperparameters presents low values.

In contrast to the previous case, optimizing Equal Opportunity requires compatible false negative rates. Optimizing this fairness metric within MCC produces the effect of promoting both privileged and protected, although protected with higher values. This produces the effect of reducing false negatives at all, since the method enhances the probability of a positive outcome. This effect is counterbalanced with intermediate demotion rates to both groups through a finetuning to keep MCC. Note that Equal Opportunity values without correction to this dataset is not as high as Statistical Parity. To optimize Equalized Odds within MCC it is necessary to keep both false negatives and false positives comparable across groups, which lead to a less intense intervention when compared to Equal Opportunity. Here remains the high values to protected promotion to achieve fairness.

Table 3.4: Fair Transition Loss hyperparameters chosen by optimizing different metrics in *Adult Income* dataset.

Objective	d_0	p_0	d_1	p_1
	Priv. Dem.	Priv. Prom.	Prot. Dem.	Prot. Prom.
MCC and Stat. Parity	0.056	0.076	0.043	0.878
MCC and Eq. Opp.	0.292	0.455	0.329	0.575
MCC and Eq. Odds	0.037	0.165	0.005	0.432
Acc. and Stat. Parity	0.470	0.110	0.023	0.446
Acc. and Eq. Opp.	0.389	0.326	0.311	0.530
Acc. and Eq. Odds	0.497	0.286	0.228	0.094

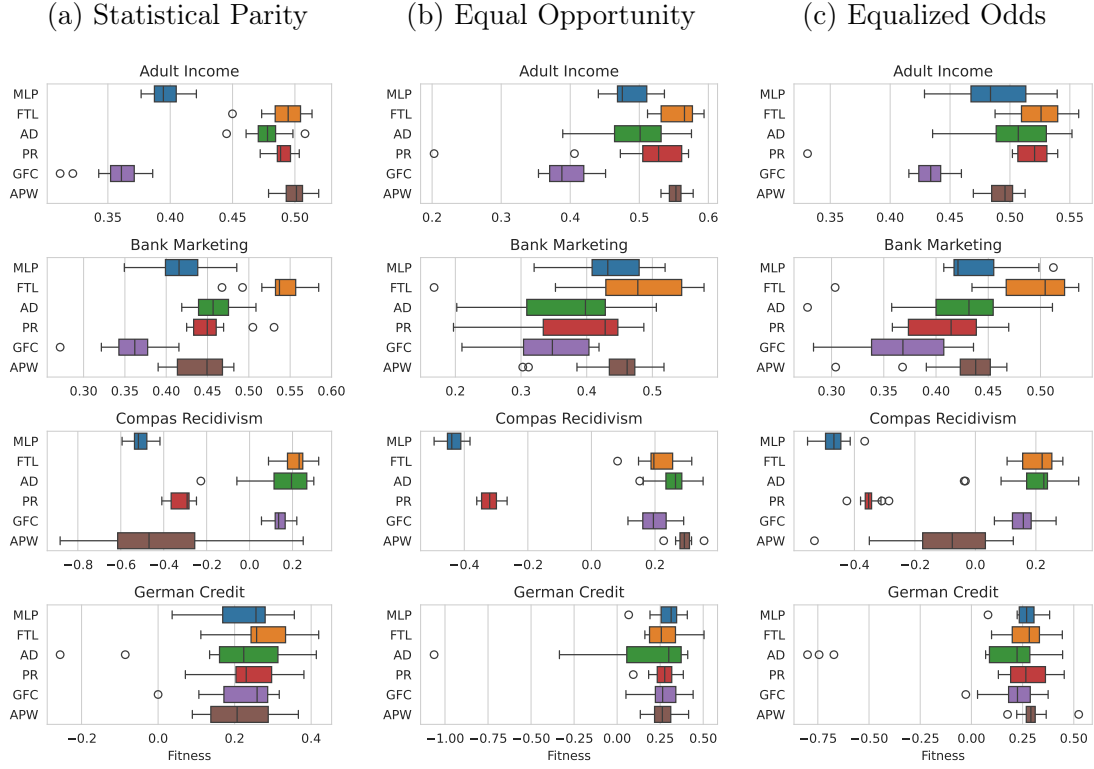

There is a remarkable difference between hyperparameters found through optimizing Accuracy and MCC. While MCC handles unbalanced classes effectively, Accuracy only measures the probability of correctly predicting an instance. If the dataset is unbalanced it is possible to achieve high Accuracy only by predicting the label of the more frequent class. In this dataset, only about a quarter of the instances are positives, which can lead to more frequent negative outcomes to achieve higher Accuracy. Results optimizing for Accuracy show significantly higher demotion rates compared to those from MCC optimization, both to privileged and protected groups. From this analysis, it's evident that the proposed methodology effectively describes and mitigates bias in a dataset according to a given fairness definition and while keeping targeted performance metric at a reasonable level.

Now we discuss the results to each objective, starting with MCC and Statistical Parity. To this objective Fair Transition Loss consistently outperforms all methods at all classification tasks, except Prejudice Remover (PR) and Adaptive Priority Reweighting (APW) in *Adult Income*. Figure 3.3a presents a box-plot comparison, where we can see that FTL, PR and APW are effectively drawn. While FTL and APW has little bit higher values, PR presents smaller variance. AS PR is a regularized logistic regression, it is a smaller model than FTL, which can explain the also smaller variance.

When comparing the optimization results for MCC and Equal Opportunity, FTL consistently outperforms its counterparts in most scenarios. Here we have only one discrepancy, as APW presents slightly advantage over FTL on COMPAS dataset. Also, on German Credit dataset all methods achieved similar results. Given the small size of this dataset, we theorize that all methods, barring AD, have reached the Pareto front — meaning, any further improvements in fairness would necessitate a proportional sacrifice in performance. This equilibrium between baseline (MLP), FTL, PR, GFC and APW is evident in Figure 3.3b.

The sub-optimal results of AD can likely be attributed to the dataset's limited size; with merely 1000 instances, this dataset might be too small for the an adversarial model like AD train effectively. This pattern of AD underperforming

Figure 3.3: Fitness values optimizing MCC and multiple fairness metrics.

persists across subsequent classification tasks involving this dataset. Interestingly, also with the exception of AD, we notice that the variance in results for most optimization scenarios is smaller than in other classification tasks. This observation further underscores our Pareto front hypothesis and suggests that the classification task’s simplicity may contribute to the reduced variability in outcomes.

When optimizing for MCC and Equalized Odds, we find that the results are consistent, with FTL outperforming its counterparts in most scenarios. Notably, within the *German Credit* dataset, FTL surpasses not just AD but also GFC. Since GFC primarily relies on the False Negative Rate for its fairness definition, it has a natural advantage when optimizing for Equal Opportunity compared to Equalized Odds, which requires maintaining equitable False Positive and False Negative Rates. As observed in the previous comparisons, Figure 3.3c underscores that the baseline, FTL, PR and APW seem to hit the Pareto front for this dataset.

Upon examining FTL’s results when optimizing for MCC across all the fairness metrics evaluated, it’s evident that FTL consistently superior results compared to its counterparts. Specifically, FTL achieves stochastically higher fitness values in 44 out of the 60 scenarios evaluated. Given the inherent challenges associated with optimizing MCC compared to Accuracy, we attribute FTL’s dominance in the MCC optimization to its capability of effectively capturing the bias idiosyncrasies of the dataset and the specified performance and fairness metrics through transition

matrices.

Furthermore, it’s noteworthy that both the baseline and PR models substantially underperform across all optimization scenarios in the *COMPAS Recidivism* classification task. This dataset, characterized by its complexity with 401 features, might be at the heart of these subpar results. We theorize that the this lack of performance could be due to an insufficiently large model to navigate such a high-dimensional space, especially when we observe, as indicated in Table 3.2, that the standard performance on this dataset is relatively low.

When turning our attention to results obtained by optimizing Accuracy, we must first reiterate its inherent simplicity as a performance metric compared to MCC. Given its nature, it allows models to attain high values simply by predicting the label of the predominant class. In such circumstances, it is comparatively easier to reach the Pareto front. Even under these conditions, FTL displays commendable competitiveness. Although it achieves stochastically higher fitness values in 25 of the 60 scenarios, this rate is notably less than what we observed when optimizing for MCC. By juxtaposing Figures 3.4a, 3.4b, and 3.4c with Table 3.3, we discern that in scenarios where FTL does not have the upper hand, it still competes closely with its counterparts. This very close results are primarily attributed to multiple methods simultaneously approaching the Pareto front. Likely when optimizing for MCC using Equal Opportunity as fairness metric, APW presents slightly advantage over FTL on COMPAS dataset.

A particularly straightforward fair classification task emerges when optimizing for Accuracy and Statistical Parity within the *Adult Income* dataset. With this pronounced class imbalance, models can lean into over-predicting the majority class, thereby aligning the probabilities of positive predictions across the groups. This strategy results in a exceptionally low variance across all methodologies. A similar, albeit reduced, effect can be observed within the *German Credit* dataset, as previously highlighted.

Fair Transition Loss consistently demonstrates effective bias mitigation, it does so by absorbing the nuances of the dataset and the fairness metric through its transition matrices, resulting in stochastically superior fitness values in a significant number of scenarios. Additionally, the method has the capacity to effectively handle datasets with unbalanced classes when optimizing for metrics like MCC. However, it’s important to recognize that Fair Transition Loss requires fine-tuning multiple hyperparameters. We thus consider that this technique is especially beneficial in setups where hyperparameter optimization is an inherent part of the prediction pipeline.

A key concern is about the potential for fairness-promoting techniques to inadvertently shift the burden onto the very group they aim to protect. This arises from

Figure 3.4: Fitness values optimizing Accuracy and multiple fairness metrics.

the possibility that by imposing additional constraints, the method might unintentionally learn alternative ways to reproduce and even reinforce the negative social biases present in the data, thus harming the individuals it intends to safeguard.

To evaluate the capability of FTL to address this risk, we present another experiment, where we adjusted only the protected promotion hyperparameter (p_1 , Equation 3.15) during the FTL training, keeping all other FTL hyperparameters at zero and dropout at 0.2. Here we follow the same re-sampling procedure, each experiment is performed over 15 repetitions, shuffling the dataset before splitting. This experiment was conducted using the four datasets previously analyzed, and we reported the following metrics assessed over the training set: protected false negative rate, protected false positive rate, protected accuracy, privileged false negative rate, privileged false positive rate, privileged accuracy, overall false negative rate, overall false positive rate and overall accuracy.

The results, presented in Figure 3.5, show that increasing the protected promotion hyperparameter value leads to a decreased false negative rate for the protected group. Meanwhile, most other monitored metrics tended towards stability to reasonable hyperparameter levels (p_1 under 0.95). An exception is the false positive rate, specially to protected group, which increased as the false negative rate decreased to keep accuracy. This pattern was consistent across all evaluated datasets. The primary aim of this experiment was to demonstrate that our proposed technique

Figure 3.5: Results of false negatives and false positives within groups on protected promotion (p_1) parameter at increasing levels.

1500 does not inadvertently penalize the protected group. Rather, the overall impact of increasing the aforementioned parameter is to effectively promote fairness for the protected group without detriment to either the privileged or protected groups. The behavior of the remaining FTL parameters is analogous, necessitating proper fine-tuning to achieve a balanced outcome. This underscores the efficacy of our method
1505 in achieving its intended purpose of reducing bias and promoting fairness in the model.

Additionally, we present performance and fairness results along with the fitness, in order to provide material to a trade-off analysis. Also, those metric values enable the reader to compare this results with different experimental setup and fitness
1510 objective from literature. Results corresponding each optimization scenario can be found on tables 3.5 to 3.10, presenting metric means and standard deviation values across multiple resample run. Best result of each metric within evaluation scenario are in bold, and standard deviation values are presented between parenthesis. Up
1515 arrow (\uparrow) indicates that the referred metric should be maximized while down arrow (\downarrow) that the metric should be minimized. To provide a visual resource to this comparison, the distribution of those metrics across multiple resample runs comparing

the propose method (FTL) with baseline (MLP) and current state-of-art (APW) are presented in joint plot format in figures 3.6 to 3.11. Here each joint plot is present within the corresponding table to a better comprehension.

Chapter 4

Correlation based penalty function

In this chapter, we propose a novel regularization factor to penalize the use of features highly correlated with a protected attribute by a machine learning model, aiming to avoid the redlining effect (PEDRESCHI *et al.*, 2008). The proposed penalization factor is applied directly to the input weights of a Multi-Layer Perceptron, using a strategy that proportionately penalizes features use based on their correlation with the sensitive feature.

4.1 Preliminaries

The phenomena known as redlining effect (PEDRESCHI *et al.*, 2008) consists in the unintended use of proxy variables to the sensitive feature by the model, which can lead model to produce indirect discrimination in their outcomes. Thus, the insight here is to penalize the use of those proxy features by the model proportionally according its correlation with sensitive feature in order to avoid redlining effed. The proposed regularization approach uses the recently described Chatterjee’s xi correlation coefficient CHATTERJEE (2021), which robustly asses whether a random variable can be described as a function of another one, as a measure of the potential of given feature to be used by the model as a proxy to the sensitive feature.

Before discussing this approach, we start defining some common correlation coefficients and providing a proper comparison within Chatterjee’s correlation. For purpose of simplicity we describe only the most commonly used form, more complex formulations involving additional terms depending on available data should be considered to most of coefficients. Also, we present some related approaches, specially those ones that, like ours, use regularization and penalty factors to avoid indirect discrimination.

The Pearson correlation coefficient, denoted by ρ and defined in Definition 20, is a measure of the linear relationship between two random variables. The Pearson correlation coefficient ranges from -1 to 1 , where 1 indicates a perfect positive linear

relationship, -1 indicates a perfect negative linear relationship, and 0 indicates no linear relationship.

1550 **Definition 20** (Pearson correlation coefficient). *Let X and Y random variables. The Pearson correlation coefficient ρ between X and Y can be defined as*

$$\rho = \frac{\text{Cov}(X, Y)}{\sigma_X \sigma_Y}, \quad (4.1)$$

where $\text{Cov}(X, Y)$ is the covariance between X and Y , while σ_X and σ_Y the standard deviations of X and Y , respectively.

1555 Spearman's rank correlation coefficient, denoted by ρ_s and defined in Definition 21, measures the strength and direction of the monotonic relationship between two ranked (ordered) variables. As like Pearson correlation coefficient, Spearman's rank correlation coefficient ranges from -1 to 1 , where 1 indicates a perfect positive relationship, -1 indicates a perfect negative relationship, and 0 indicates no relationship.

1560 **Definition 21** (Spearman's correlation coefficient). *Let X and Y random variables, n the sample size and X_i, Y_i the i -th observations to $i = 1 \dots n$. Let R_{X_i}, R_{Y_i} the rank of observations X_i, Y_i , i.e. the position of X_i, Y_i by ordering the samples, respectively. The Spearman's rank correlation coefficient ρ_s between X and Y can be defined to non-repeated observation values as*

$$\rho_s = 1 - \frac{6 \sum_{i=1}^n d_i^2}{n(n^2 - 1)}, \quad (4.2)$$

1565 where $d_i = R_{X_i} - R_{Y_i}$.

Kendall's rank correlation coefficient, denoted by τ and defined in Definition 22, indicates the strength and direction of association between two variables. It is based on the relative ordering of pairs of observations rather than their actual values. Here we interpret the correlation values as like in Spearman's and Pearson's correlation coefficients, ranging from -1 to 1 , where 1 indicates a perfect positive relationship, -1 a perfect negative relationship, and 0 no linear relationship.

1575 **Definition 22** (Kendall's correlation coefficient). *Let two variables X and Y sampled with n pairs of observations (X_i, Y_i) for $i = 1, 2, \dots, n$. A pair of observations (X_i, Y_i) and (X_j, Y_j) is **concordant** if the ranks (order) of both elements agree, i.e., to $i < j$ either $X_i > X_j$ and $Y_i > Y_j$ or $X_i < X_j$ and $Y_i < Y_j$. Otherwise they are considered **discordant**, i.e., either $X_i > X_j$ and $Y_i < Y_j$ or $X_i < X_j$ and $Y_i > Y_j$.*

The Kendall's rank correlation coefficient τ between X and Y can be defined as

$$\tau = \frac{2(N_c - N_d)}{n(n-1)}, \quad (4.3)$$

where N_c is the number of concordant observation and N_d the number of discordant observations.

1580 Chatterjee's rank correlation coefficient, denoted by ξ and defined in Definition 23, is designed to robustly measure the degree of dependence between two variables without assuming any specific type of relationship and capturing noise nuances. The previously described correlation coefficients are not effective on detecting associations that are not monotonic, even in complete absence of noise.

1585 This correlation coefficient assesses whether a random variable can be described as a function of another one. Differently from correlation coefficients described before, this coefficient ranges from 0 to 1, where 0 indicates independence and 1 indicates a perfect functional relationship. Also this correlation is not symmetric, i.e., the correlation between X and Y may differ from between Y and X .

1590 **Definition 23** (Chatterjee's correlation coefficient). *Let two variables X and Y , where Y is not a constant, sampled with n pairs of observations (X_i, Y_i) for $i = 1, 2, \dots, n$. The Chatterjee's rank correlation coefficient τ between X and Y when there are no ties among Y can be defined as*

$$\xi = 1 - \frac{3 \sum_{i=1}^{n-1} |R_{i+1} - R_i|}{n^2 - 1}, \quad (4.4)$$

1595 where R_i is the rank of Y_i in the ordered sequence of Y values corresponding to the sorted X values.

To illustrate some characteristics of Chatterjee's rank correlation coefficient we compare those results on Anscombe's quartet (ANSCOMBE, 1973) along with Pearson's, Spearman's and Kendall's correlation coefficients. The Anscombe's quartet (Table 4.1) is a set of four different datasets that have nearly identical simple descriptive statistics, yet very different distribution, which is clear on Figure 4.1. As an additional resource, a line representing a linear regression over the data is plotted within the points, enforcing that they present nearly identical simple descriptive statistics.

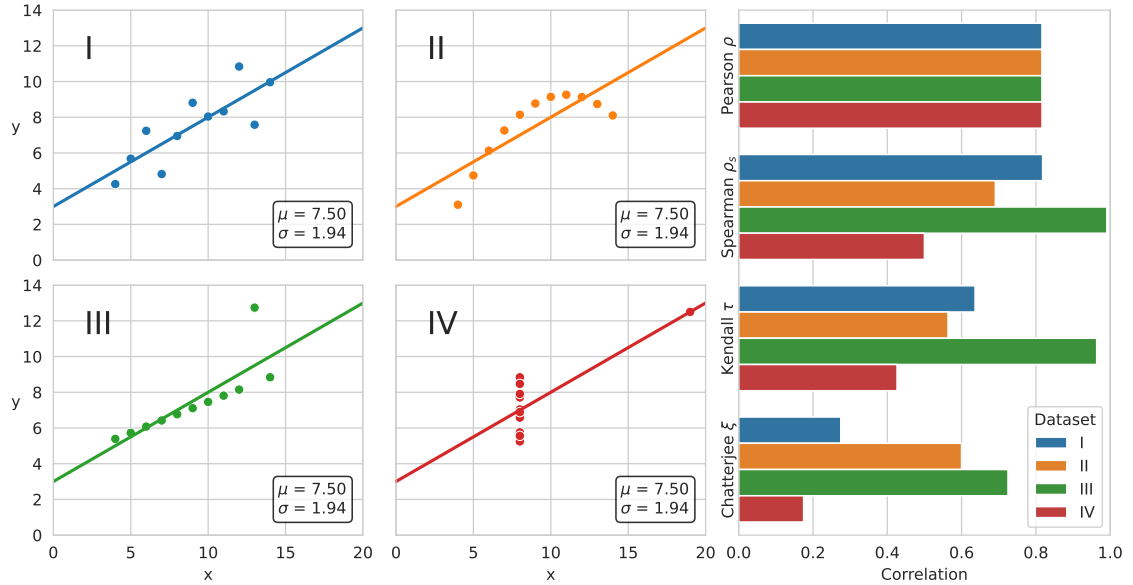

1600 Comparing correlation coefficients, it is evident that Pearson's ρ does not properly capture the peculiarities of Anscombe's quartet. Although the four datasets present the same correlation coefficient, they exhibit very different distribution. Spearman's ρ_s and Kendall's τ performs very similarly each other, properly capturing relevant characteristics, albeit Kendall's τ demonstrates to be more exigent

Table 4.1: Anscombe’s quartet

I		II		III		IV	
x	y	x	y	x	y	x	y
10.0	8.04	10.0	9.14	10.0	7.46	8.0	6.58
8.0	6.95	8.0	8.14	8.0	6.77	8.0	5.76
13.0	7.58	13.0	8.74	13.0	12.74	8.0	7.71
9.0	8.81	9.0	8.77	9.0	7.11	8.0	8.84

14.0	9.96	14.0	8.10	14.0	8.84	8.0	7.04
6.0	7.24	6.0	6.13	6.0	6.08	8.0	5.25
4.0	4.26	4.0	3.10	4.0	5.39	19.0	12.50
12.0	10.84	12.0	9.13	12.0	8.15	8.0	5.56
7.0	4.82	7.0	7.26	7.0	6.42	8.0	7.91
5.0	5.68	5.0	4.74	5.0	5.73	8.0	6.89

on assigning high correlation values. Chatterjee’s ξ is even more exigent, pursuing
the behavior of capturing functional relations between data, considering noise. For
example, the first quartet presents a small ξ as it contains relevant noise, despite the
points are effectively linearly disposed. Albeit the second quartet demonstrate a non
linear distribution, the data has lower noise influence, presenting a more functional
relationship. Thus, to Chatterjee’s correlation the second presents a higher coeffi-
cient than the first, which is not equivalently captured by Spearman’s and Kendall’s.

Figure 4.1: Multiple correlation coefficients on Anscombe’s quartet.

As a resource to defining the proposed redlining penalty method we describe the L2 regularization. This regularization term, a.k.a. weight decay, is a common

technique used to prevent overfitting in machine learning models, including Multi-
 1620 Layer Perceptrons (MLPs). The L2 regularization adds a penalty term to the loss
 function that is proportional to the sum of the squares of the model parameters
 (weights). This encourages the model to keep the weights small, which can help
 improve generalization.

Let $\mathbf{W}^{(l)}$ represent the weight matrix for the l -th layer of the MLP, and let $\mathbf{b}^{(l)}$
 1625 denote the corresponding bias vector. The primary loss function of the network, L_0 ,
 could be any suitable loss function such as the mean squared error for regression or
 the cross-entropy loss for classification. The L2 regularization term for a single layer
 is given by

$$R(\mathbf{W}^{(l)}) = \frac{1}{2} \sum_{i=1}^{d_l} \sum_{j=1}^{h_l} \left(W_{ij}^{(l)} \right)^2, \quad (4.5)$$

where d_l and h_l are the dimensions of the weight matrix $\mathbf{W}^{(l)}$, and $W_{ij}^{(l)}$ is the weight
 1630 connecting the i -th input neuron to the j -th neuron in the l -th layer. Thus, the total
 regularization term for the entire network, considering all layers, is

$$R(\mathbf{W}) = \frac{1}{2} \sum_{l=1}^L \sum_{i=1}^{d_l} \sum_{j=1}^{h_l} \left(W_{ij}^{(l)} \right)^2, \quad (4.6)$$

where L is the total number of layers in the network. Furthermore, the total loss
 function L for the MLP, incorporating the L2 regularization term, is defined as

$$L = L_0 + \lambda R(\mathbf{W}), \quad (4.7)$$

where λ is a scalar hyperparameter that controls the overall strength of the regular-
 1635 ization.

By adding this regularization term, the optimization process aims to minimize
 the primary loss L_0 along with keeping the weights small, thereby helping to reduce
 the model complexity and prevent overfitting. The gradient descent updates for the
 weights will be adjusted to account for the regularization term, effectively shrinking
 1640 the weights during the training process.

KAMISHIMA *et al.* (2012)

4.2 Redlining Penalty Regularizer

Here we propose the Redlining Penalty Regularizer (RPR), a novel regularization
 term that penalizes the weights of features highly correlated with the sensitive at-
 1645 tribute in order to prevent the redlining effect. By incorporating this penalty into
 the loss function of the neural network, the model is encouraged to reduce its reliance

on sensitive attributes, thus promoting fairer predictions.

As referred before, the Chatterjee Xi Correlation Coefficient distinguish from many other by providing a measure of how much one random variable can be expressed as a function of another, with a range from 0 to 1. This characteristics is relevant to the proposed use, to capture redlining effect, as of this phenomena happens exactly when the sensitive feature can be inferred by another one, producing the same harmful effects whether the correlation is positive or negative. Naturally it would be possible to use the absolute value of correlation coefficient such as Pearson, Spearman and Kendall, but this strategy could lead to some kind of information loss. Another relevant characteristics of this correlation coefficient is the ability to capture sophisticated nonlinearities, including nonmonotonic ones, and the effects of noise on variable's distribution, conditions frequently present in proxy feature relationships.

Thus, let $X \in \mathbb{R}^{n \times d}$ be a dataset where n represents the number of instances and d represents the number of features. Let $X_i \in \mathbb{R}^n$ denote the i -th feature of the dataset, and let $A = X_i \in \mathbb{R}^n$ be a sensitive (protected) feature for some i . In this neural network, $\mathbf{W}^{(1)} \in \mathbb{R}^{d \times h}$ is the weight matrix for the first hidden layer, with h being the number of neurons in this layer. Additionally, λ is a scalar that controls the overall strength of the regularization.

Thus, the proposed regularization term $R(\mathbf{W}^{(1)})$ applied to the weight matrix $\mathbf{W}^{(1)}$ only on the first hidden layer, defined as

$$R(\mathbf{W}^{(1)}) = \sum_{i=1}^d \xi_n(X_i, A) \sum_{j=1}^h (W_{ij}^{(1)})^2, \quad (4.8)$$

where $W_{ij}^{(1)}$ are the weights connecting the i -th input feature to the j -th neuron in the first hidden layer. Here, the Chatterjee's Xi Correlation Coefficient $\xi_n(X_i, A)$ between the i -th input feature X_i and the sensitive feature A acts as the regularization strength for the i -th input feature. The greater i -th input feature dependence on sensitive feature the greater the penalization factor enforcing lower values to those weights.

Thus, the total loss function L to a MLP, incorporating the sensitive-feature-specific L_2 regularization, is defined as

$$L = L_0 + \lambda R(\mathbf{W}^{(1)}), \quad (4.9)$$

where L_0 is the primary loss function of the network. This formulation ensures that the model's learning process penalizes weights with high values associated with features highly correlated to the sensitive attribute, thereby reducing the potential for biased decisions influenced by redlining effect.

This formulation differs from similar approaches to regularization in order to achieve fairness in machine learning by two fundamental points. The first one is that here the regularization acts as a focused penalty factor through the use of the correlation of each feature to the sensitive one, reducing its effect on less correlated features and boosting on the highly correlated ones. The second point is that this proposed penalty does not act as a common regularizer, by imposing small values on every model’s parameter. Rather, it penalizes the use of each feature according to its correlation to the sensitive one by exclusively acting on the input layer weights, that is, the usage level of each feature by hidden units.

With the combination of characteristics tailored by this formulation and the chosen correlation coefficient we do expect effectively avoiding the use of indirect sensitive feature predictors within the model, thus mitigating redlining effect.

4.3 Experimental setup

In this section, we detail the experimental setup employed to benchmark the proposed regularization within both Standard MLP with Cross Entropy Loss and a MLP using Fair Transition Loss. Both MLP model uses two hidden layers with 100 hidden units each, *ReLU* activation function, batch size of 64, 50 epochs early stopped at 3 epochs without improvement (LI *et al.*, 2020) and softmax in output, trained with ADAM optimizer (KINGMA & BA, 2015) and learning rate at $3e-4$.

The overall experimental methodology follows same principles of those used on Fair Transition Loss evaluation. There are two phases: hyperparameter tuning and testing. In the hyperparameter tuning phase we perform a Bandit-Based pruning approach using HyperBand (LI *et al.*, 2018) with Tree-structured Parzen Estimator Sampler (TPE) (BERGSTRA *et al.*, 2011) over 100 trials. At each trial a fitness function is evaluated by performing a complete training and validation, where both model performance and fairness metrics are assessed. The fitness function is computed based on the objective defined in Equation 3.16.

Once the best hyperparameters are selected, we proceed to the testing phase, where a new training is conducted using those optimal hyperparameters. After this training, we evaluate the model’s performance on a separate test set that was not used during the hyperparameter tuning phase, which are reported. This complete tuning-training-testing described is repeated 15 times within random re-sampling then we proceed to comparison. Here the re-sampling consists in shuffling the whole dataset before splitting, as described before

As the objective defined in Equation 3.16 can be achieved with different performance and fairness metrics, we compare the proposed regularization schema within Standard MLP and MLP with FTL in different optimization scenarios, consider-

ing as performance metrics Accuracy (Acc.) and Mathews Correlation Coefficient (MCC), while the fairness metrics considered are Statistical Parity (Stat. Parity), Equal Opportunity (Eq. Opp.) and Equalized Odds (Eq. Odds). Those pursued
1720 metrics lead us to the following optimization scenarios: MCC and Statistical Parity; MCC and Equal Opportunity; MCC and Equalized Odds; Accuracy and Statistical Parity; Accuracy and Equal Opportunity; Accuracy and Equalized Odds.

Table 4.2: Hyperparameters search ranges or options of each method.

Method	Parameter	Range/options
Standard MLP without regularization (baseline)	dropout	[0.0, 0.2]
Standard MLP with RPR	dropout	[0.0, 0.2]
Fair Transition Loss without regularization	λ	$\{1e^{-2}, 1e^{-3}, 1e^{-4}\}$
	d_0, p_0, d_1, p_1	[0.0, 1.0]
	dropout	[0.0, 0.2]

	dropout	[0.0, 0.2]
	λ	$\{1e^{-2}, 1e^{-3}, 1e^{-4}\}$

Table 4.2 presents the methods hyperparameters along with their corresponding search ranges or options. While each method may possess a varying number of
1725 hyperparameters and range sizes, all are optimized under the same conditions and number of configurations to guarantee a balanced comparison.

To properly compare this set of 15 results of each method, we conduct an Almost Stochastic Order (ASO) test (DROR *et al.*, 2019), a significance test suitable for comparing complex machine learning models with various hyperparameters. As
1730 described before, the ASO test involves evaluating a set of metrics through multiple samplings of a Collection of Statistics (in this case assessed in test phase using random resampling) to compare one method against another. The $ASO(A, B)$ function yields a value in the range $[0, 1]$, given two methods A and B . If $ASO(A, B)$ is lesser than 0.5, we can reject the null hypothesis and conclude that method A outperforms
1735 method B in the given task. That is, method A produces stochastically larger values than method B for a given metric. The lower the $ASO(A, B)$ value, the stronger the evidence that A is superior to B in that particular task, which can be interpreted as a confidence interval. Therefore, we perform comparisons between all methods for each optimization scenario outlined previously and for each dataset.

Our experiments uses common datasets used in Fair Classification problems, namely *Adult Income* (BECKER e KOHAVI, 1996), *German Credit* (HOFMANN, 1994), *Bank Marketing* (S. MORO e CORTEZ, 2012), and *COMPAS Recidivism* (?). We use the dataset readers available in the AI Fairness 360 toolkit (BELLAMY *et al.*, 2018) with its standard configurations. Instances with missing data are removed.
1740
1745 To a proper description of those datasets please check Section 3.3

For all datasets, the data preparation process is the same, one-hot encoding for categorical features and standardize the numerical features. We perform a random split, with 80% allocated for the hyperparameter tuning phase and the remaining 20% reserved for evaluating metrics in the test phase. Within the hyperparameter tuning phase, this corresponding fraction of data is further randomly split, with 80% assigned to training and 20% to validation. The validation set allows us to assess metrics and compute the fitness function for each hyperparameter configuration. In datasets where there is originally some kind of split (e.g., train set and test set in separate files), all available data is merged and then shuffled to produce new splits at each run.

4.4 Results and discussion

Before presenting the main experimental results, we perform an additional comparison using the same methodology to address two concerns. Firstly, one might argue that the proposed penalty strategy is not distinctly effective compared to regular regularization factors like L2. In this context, any observed advantages of the proposed method over the same model without the penalty could be attributed to the conventional effects of regularization, i.e. avoiding model overfitting and consequently improving fitness values. Therefore, we compare the proposed strategy not only with an MLP baseline but also with the same MLP using standard L2 regularization across all network layers, optimized using the ranges specified in Table 4.2.

Secondly, there is the question of whether using traditional correlation coefficients in order to assessing and penalizing redlining, such as Pearson’s ρ , Spearman’s ρ_s , and Kendall’s τ , would be equally beneficial. To address this, we compare the proposed penalty (referred as RPR_ξ) with variations that use the absolute values of Pearson’s ρ , Spearman’s ρ_s , and Kendall’s τ instead of Chatterjee’s ξ , referred to as RPR_ρ , RPR_{ρ_s} , and RPR_τ , respectively. In this comparison, every method uses the same MLP architecture and the same hyperparameter tuning procedure, varying only the regularization strategy.

As we have multiple optimization scenarios with different objective functions and datasets, and to each of them multiple runs, we present in Table 4.3 the results of the ASO test described before, which allow us to properly compare each regularization strategy to RPR_ξ . Values under 0.5 (in bold) mean that we can reject the null hypothesis, i.e., RPR_ξ produces stochastically larger fitness than the regularization strategy in respective column for a objective and dataset. Lower values indicate stronger evidence. Additionally, complete results will be available at the end of this section, as like those presented to the Fair Transition Loss experiments.

Table 4.3: Almost Stochastic Order test comparing RPR_ξ fitness to baseline and multiple regularization schemes. Values under 0.5 (in bold) mean that RPR_ξ outperforms corresponding method in such optimization scenario.

Fairness/Performance Metric	Dataset	MLP (baseline)	MLP L2	MLP RPR_ρ	MLP RPR_{ρ_s}	MLP RPR_τ
Statistical Parity MCC	Adult Income	0.80	0.68	1.00	0.61	0.65

	German Credit	0.26	0.11	0.50	0.25	1.00

Notably, both baseline MLP and MLP with L2 regularization performs similarly when compared to RPR_ξ on almost every scenario. This observation lead us to a comprehension that the proposed penalty schema differs from standard regularization strategies such as L2. Another relevant perception is that the proposed method is highly influenced by the dataset, which will be explored furthermore on this section.

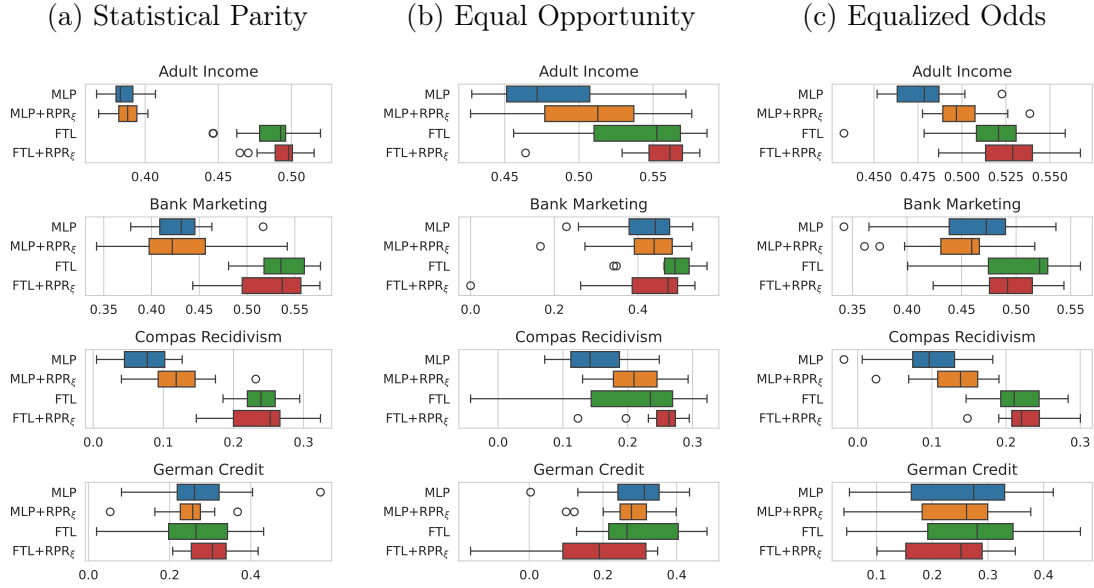

Now we compare the results of the proposed penalty schema with standard correlation coefficients. We can perceive that in almost all scenarios where RPR_ξ outperforms baseline MLP and MLP with L2 regularization it also outperforms the same penalty strategy but using standard correlation coefficients instead of Chatterjee's. This enforces the argument that the proposed approach takes advantages of the Chatterjee's correlation coefficient characteristics. Despite that observation, in most of scenarios the ASO values are higher to those produced by baseline MLP and MLP with L2 regularization, indicating that they presents better performance/fairness trade-off. This can be interpret as an ability of the proposed regularization schema

on penalizing redlining effect, although less efficiently than when using Chatterjee’s correlation coefficient.

Table 4.4: Almost Stochastic Order test comparing the use of Redlining Penalty Regularizer on Standard MLP and MLP with Fair Transition Loss fitness. Values under 0.5 (in bold) mean that the model with RPR outperforms the same model without regularization on each optimization scenario.

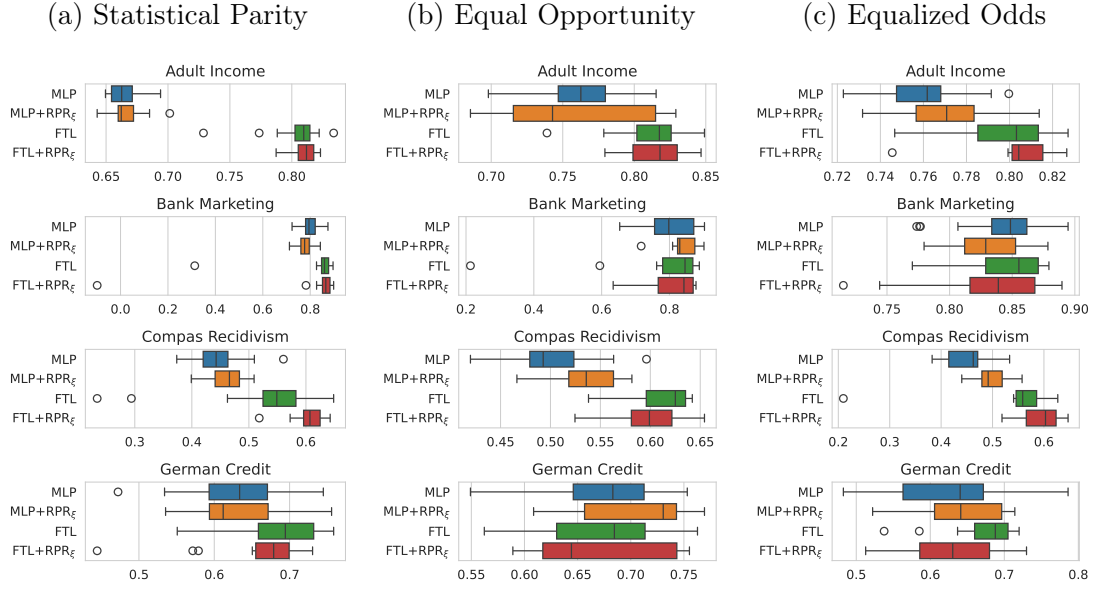

Fitness Rule	MLP				FTL			
	Adult	Bank	COMPAS	German	Adult	Bank	COMPAS	German
MCC - S. Parity	0.79	0.99	0.03	1.00	0.34	1.00	1.00	0.31
MCC - Eq. Opp.	0.26	1.00	0.01	1.00	0.35	1.00	0.19	1.00

Figure 4.2: Fitness values of RPR optimizing MCC and multiple fairness metrics.

Now we compare the effects of Redlining Penalty Regularizer on both MLP with standard cross entropy loss and fair transition loss. The MLP baseline here is the same presented on the last comparison (Table 4.3), and the FTL model uses the same MLP architecture. The overall methodology remains the same, including 15 runs with dataset resampling with 100 trials to hyperparameter tuning each, according Table 4.2. The FTL model without RPR is exactly that same presented at Chapter 3 and on CANALLI *et al.* (2024), whose achieved state-of-art results. In order to provide a straightforward comparison we include only RPR_{ξ} , as it reaches the best results when compared with the others. The ASO results are available at Table 4.4 and the box-plot comparison at Figure 4.2 and Figure 4.3.

Figure 4.3: Fitness values of RPR optimizing Accuracy and multiple fairness metrics.

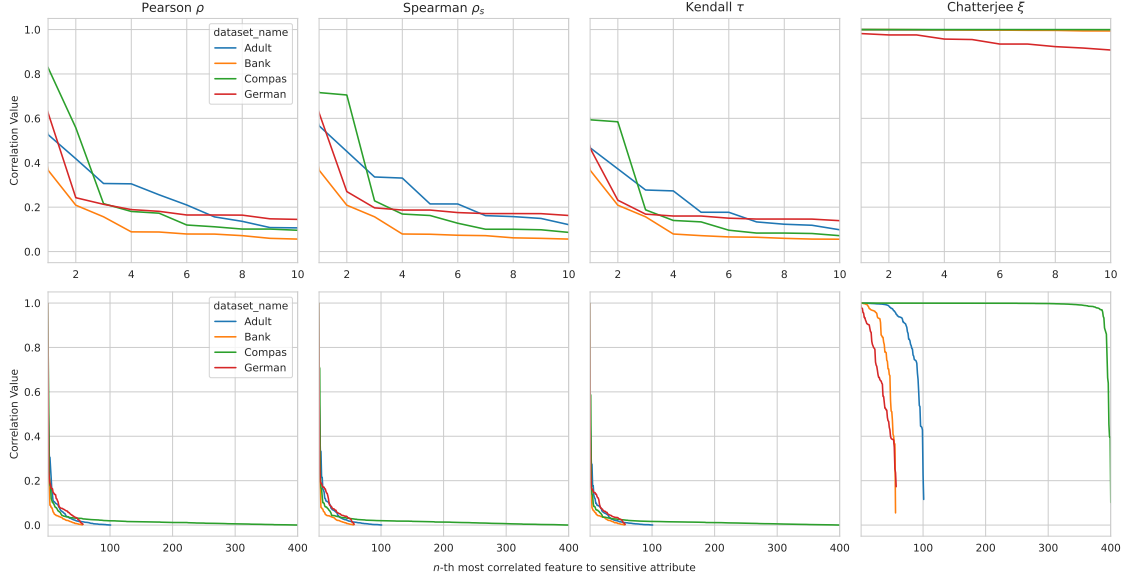

As an additional resource to interpret these results we plot at Figure 4.4 the correlations of each feature to the sensitive to each described correlation coefficient at each dataset. The correlation values are presented from highest value to the lower, to provide a non-ascendant visualization. Also, we omit the correlation of sensitive feature to it self (always 1.0) and plot both the top 10 correlations and the values to each feature, according the number of features at corresponding dataset. Note that Chatterjee's performs very differently when compared to the others, identifying more highly correlation values, demonstrating the functional relationship of many features with the sensitive and therefore theirs potential to be used as proxy features by the model. Another relevant perception is that the *Bank dataset* presents considerably lower correlations, although still very high values than the others.

On Table 4.4 RPR presents low ASO values in many scenarios, on which we can claim that it outperforms the corresponding model without penalty. It is clear that both MLP and FTL benefit with the use of RPR, whose results remains strongly better to most of optimization objectives. Here the main difference is the dataset. While to *Adult* and *COMPAS* the model with RPR consistently outperforms its counterparts, this not happens when the proposed technique is evaluated on *Bank* and *German* datasets. As referred before, *German Credit* is a very small and simple dataset. In this condition the Pareto frontier is rapidly achieved, with no room left for improvement. This condition clear looking at at Figure 4.2 and Figure 4.3.

Additionally, when comparing *Bank's* features correlations to sensitive at Figure 4.4 we can argue that as it presents reduced redlining effect, the effectiveness of the proposed penalty strategy is also reduced. Analogously, the best RPR results are those assessed on *COMPAS*, the dataset with the most aggressive redlining effect.

Figure 4.4: Sorted feature’s correlation to the sensitive one according multiple correlation coefficients to all datasets.

Thus, on those conditions where the dataset presents features with high potential to be learned as proxy to the sensitive feature by the model, Redlining Penalty Regularizer consistently outperforms the model without regularization. This happens to both MLP models, the one using standard cross entropy loss and with Fair Transition Loss. In this last scenario the state-of-art results described before are enhanced.

As done on the last chapter, we present performance and fairness results along with the fitness, in order to provide material to a trade-off analysis. Those metric values enable the reader to compare this results with different experimental setup and fitness objective from literature. Results corresponding each optimization scenario can be found on tables 4.5 to 4.10, presenting metric means and standard deviation values across multiple resample run. Best result of each metric within evaluation scenario are in bold, and standard deviation values are presented between parenthesis. Up arrow (\uparrow) indicates that the referred metric should be maximized while down arrow (\downarrow) that the metric should be minimized. To provide a visual resource to this comparison, the distribution of those metrics across multiple resample runs comparing the Redlining Penalty Regularization using Chatterjee’s correlation (FTL) on baseline (MLP) and Fair Transition Loss (FTL) are presented in joint plot format in figures ?? to ?. Each joint plot is present within the corresponding table to a better comprehension.

Table 4.5: Mean and standard deviation metric values optimizing MCC and Statistical Parity in comparison with Redlining Penalty Regularizer.

In this study, we present Fair Transition Loss, a novel in-processing technique for addressing fair classification problems. It hoisting concepts from label noise robustness to mitigate social bias against underprivileged groups. We explore the intersection of these two research areas, highlighting both their similarities and differences. Our approach tackles the fairness-performance trade-off as a multi-objective optimization problem, employing a linear relaxed objective function to reduce bias while maintaining acceptable predictive performance levels. We benchmark this approach and compare to prominent in-processing techniques in common fair classification tasks, using the Almost Stochastic Order test to evaluate results through multiple resampling iterations. This ensures that all methods operate under the same conditions, maximizing their potential within the scope of hyperparameter tuning.

This is the first technique that models fair classification problems by drawing insights from classification in the presence of label noise. Our experiments indicate that Fair Transition Loss consistently outperforms its competitors in most optimization scenarios. Even in those cases that the proposed method isn't the outright leader, it performs at least as well as evaluated alternatives. Therefore, this novel approach can significantly mitigate bias while keeping model performance, particularly in scenarios optimizing balanced performance metrics like MCC. The proposed technique particularly stands out in setups where hyperparameter tuning is an integral component of the prediction pipeline.

While our proposed method seems competitive in problems involving hyperparameter optimization for binary fair classification tasks using a simple Multi-Layer Perceptron, we can outline some potential research directions: evaluate Fair Transition Loss within different neural network architectures, such as Deep Neural Networks; investigate whether the proposed method can effectively address multi-class fair classification problems and handle multiple sensitive attributes, as theoretically possible; evaluate FTL within different multi objective optimization schemes, such as the Fair Hyperparameter Tuning techniques proposed by F.CRUZ *et al.* (2021) or

the non-linear Chebyshev scalarization scheme proposed by WEI e NIETHAMMER
1885 (2022); explore approaches to estimating or initializing transition matrices without
relying on hyperparameter tuning techniques.

With this work, we hope to establish Fair Transition Loss as a relevant tool in
fair classification tasks and pave the way for novel approaches that draw insights
from label noise for various fair machine learning problems, including regression,
1890 recommender systems, ranking and language models.
